(1) No support structure is assumed for the free-standing diffracting bars in Fig. 3.

(2) The bars are assumed to be plane-parallel, congruent, homogeneous, and isotropic samples of the test material.

(3) The surfaces of the bars are assumed to be perfectly planar.

(4) Surface phase shifts and multiple reflections are ignored.

(5) The source radiation is assumed to be monochromatic and planar at the sample plane.

(6) The aperture and bar dimensions d and $(a\text{-}d)$ are assumed to be large enough for the eikonal approximation to apply in transmission through the grating bars. Additionally, all the conditions for the validity of scalar diffraction theory are assumed to hold [40]. As opposed to assumptions 1–5, these idealizations are to be considered as prerequisites for all valid MSFTI implementations.

Although this is evidently a large set of idealizations, departures from most of the listed assumptions have been analyzed in prior work and the results are available in the literature [1–3]. In most practical cases the corresponding corrections in the soft X-ray range can be expressed quantitatively as simple correcting terms or factors in the basic equations. In view of the referential purpose of this handbook chapter, some of the more important of these will be included in this section.

We begin by quantifying the notion of sensitivity, whose physical meaning can be interpreted as the "fractional change in a parameter x induced by a fractional change in a parameter y." Analytically, the differential form of this quantity is given by

$$S_y^x = \frac{y}{x}\left(\frac{\partial x}{\partial y}\right) \equiv \frac{\partial(\ln x)}{\partial(\ln y)}. \tag{8}$$

Referring to Fig. 3, we can now write out the expression for the magnitude squared of the Fourier transform of the electric field x-distribution along the sample plane in direct analogy to Eq. 2. For the intensity of the mth peak in the far field, this expression reduces to [41]

$$I^{(m)} = \left(\frac{\sin(\pi m N)}{\sin(\pi m)}\right)^2 |\bar{M} + e^{\pi i m}\bar{A}|^2, \qquad m = 0, \pm 1, \pm 2, \ldots, \tag{9}$$

where $\bar{M}$ and $\bar{A}$ are, respectively, the Fourier transforms of the electric

field distributions across a bar surface and an open aperture. For a given period a and an arbitrary aperture dimension d, we obtain the following expression for the ratio of the mth order peak intensity to the zeroth order peak intensity:

$$\frac{I^{(m)}}{I^{(0)}} = \frac{[1 - 2e^{-2\pi W k(\lambda)} \cos 2\pi W \delta(\lambda) + e^{-4\pi W k(\lambda)}] \operatorname{sinc}^2(md/a)}{[1 + 2(a/d - 1)e^{-2\pi W k(\lambda)} \cos 2\pi W \delta(\lambda) + (a/d - 1)^2 e^{-4\pi W k(\lambda)}]}, \qquad m \neq 0. \tag{10}$$

This expression demonstrates that for the assumed rectangular bar cross-section, the peak intensity ratios among orders other than the first will be independent of $k(\lambda)$ and $\delta(\lambda)$, and that the entire effect of $\hat{n}$ on the far-field intensity spectrum can be deduced solely from the ratio $I^{(1)}/I^{(0)}$. The establishment of the experimental equations based on Eq. 10 is immediate. If we choose two gratings of the same material and of parameters a_1, d_1, W_1, and a_2, d_2, W_2 and denote the corresponding intensity ratios by

$$I_i^{(1)}/I_i^{(0)} = R_i, \qquad i = 1, 2, \tag{11}$$

we get

$$\cos 2\pi W_i \delta(\lambda) - \frac{1}{1 + A_i} \cosh 2\pi W_i k(\lambda) + \frac{A_i}{1 + A_i} \cosh[2\pi W_i k(\lambda) + r_i] = 0, \tag{12}$$

where

$$A_i = R_i \tfrac{1}{4}\pi^2 [\sin(\pi\eta_i) \cosh(\tfrac{1}{2} r_i)]^{-2}, \tag{13}$$

$$\eta_i = d_i / a_i, \tag{14}$$

and

$$r_i = \ln\left(\frac{\eta_i}{1 - \eta_i}\right), \tag{15}$$

It is evident that accurate measurements of the *lengths* a_i, d_i, W_i and the far-field *intensities* $I_i^{(0)}$ and $I_i^{(1)}$ constitute, in principle, a sufficient data set for iterating the values of k and $|\delta|$ out of Eq. 12.

The sensitivities of the measured peak-intensity ratios R_i to the sample grating parameters are straightforwardly derived by directly applying Eq. 8 to Eq. 12. The results are

$$S_\delta^{R_i} = \left(\frac{2\pi W_i\delta \sin 2\pi W_i\delta}{\cosh 2\pi W_i k - \cos 2\pi W_i\delta}\right)\left(\frac{\cosh 2\pi W_i k + \cosh(2\pi W_i k + r_i)}{\cosh(2\pi W_i k + r_i) + \cos 2\pi W_i\delta}\right), \quad (16)$$

$$S_k^{R_i} = \left(\frac{2\pi W_i k \sinh 2\pi W_i k}{\cosh 2\pi W_i k - \cos 2\pi W_i\delta}\right)$$

$$\times \left(\frac{2\cos 2\pi W_i\delta + \cosh(2\pi W_i k + r_i) - \cosh 2\pi W_i k}{\cosh(2\pi W_i k + r_i) + \cos 2\pi W_i\delta}\right), \quad (17)$$

$$S_{W_i}^{R_i} = [2\pi W_i\delta \sin 2\pi W_i\delta(\cosh(2\pi W_i k + r_i) + \cosh 2\pi W_i k)$$

$$+ 2\pi W_i k \cosh 2\pi W_i\delta(\sinh(2\pi W_i k + r_i)$$

$$+ \sinh 2\pi W_i k) - 2\pi W_i k \sinh 2\pi W_i k]$$

$$\div [(\cosh(2\pi W_i k + r_i) + \cos 2\pi W_i\delta)(\cosh 2\pi W_i k - \cos 2\pi W_i\delta)], \quad (18)$$

and

$$S_{\eta_i}^{R_i} = 2([\pi\eta_i \cot \pi\eta_i] - 1)$$

$$+ \left[\frac{2\eta_i(e^{-2\pi W_i k} + (\eta_i^{-1} - 1)^{-1}\cos 2\pi W_i\delta)}{((\eta_i^{-1} - 1)^{-1}e^{2\pi W_i k} + (\eta_i^{-1} - 1)e^{-2\pi W_i k} + 2\cos 2\pi W_i\delta)}\right]. \quad (19)$$

Equations 11–15 constitute the basic experimental relations for a minimal set of two gratings. Utilizing more than two gratings in an experimental determination will, as expected, result in the statistical reduction of the uncertainties stemming from random errors. For example, if M' gratings are used, there will be $M'(M'-1)/2$ cross-correlated calculations of δ and k, and the sensitivity equations must then be employed in an iterative rondo with Eqs. 11–15 to make all the calculated values of δ and k consistent with each other and the known systematic errors [2]. The second, evident use of the sensitivity equations is to help choose optimal parameters or parameter ranges for sample gratings to be fabricated for an experiment, provided some initial knowledge of the actual values of the constants exists.

We next turn to the question of corrections to the basic experimental

equations, which can arise from departures from the ideal conditions assumed at the outset of this section. We will focus on those corrections liable to be of immediate concern for preliminary evaluations of MSFTI experiments. More complete treatments of nonideal experimental conditions have been cited above. The first important modification arises when multiple reflections in the grating bars have to be taken into account (as in the visible and UV [6] ranges), or when the phase shifts induced by the sample surfaces do not all cancel (as can happen, for instance, when the sample bars are deposited on a plane–parallel substrate). If we can represent all these effects by applying a complex factor, $\tau \exp(i\Phi)$, to $\bar{M}$ in Eq. 9, we arrive at the following modified version of Eq. 10, wherein we have introduced the quantity $\Omega = -\frac{1}{2}\ln(\tau)$ and utilized the (unindexed) Eq. 15:

$$\frac{I'^{(1)}}{I'^{(0)}} = e^{r}\,\mathrm{sinc}^2\left(\frac{d}{a}\right)\frac{\cosh(2\pi Wk+\Omega)-\cos(2\pi W\delta-\Phi)}{\cosh(2\pi Wk+r+\Omega)+\cos(2\pi W\delta-\Phi)}. \qquad (20)$$

We see immediately that since both τ and Φ depend on both δ and k [2, 10], the establishment of an equation separable in δ and k (such as Eq. 15) will not in general be possible when τ differs from 1 and/or Φ from 0. This can in certain instances lead to an enhanced sensitivity of the experimental results to systematic errors, thereby degrading the validity and reliability of computed results. This fact highlights one of the more important potential advantages of MSFTI in the 100–3000 eV region, which we herewith add to those already listed in Sections I and III:

(v) For many materials throughout broad portions of the VUV–soft X-ray range, Ω and Φ are often close enough to zero to be ignored, a factor underlying the simplicity of the basic experimental formalism of MSFTI. This in effect can reduce the number of physical variables influencing measurements, enhancing the validity of MSFTI in the corresponding spectral region.

The following modifications of the ideal experimental equations are based on the statistical departure of real-life sample bars from cross-sectional rectangularity, dimensional congruency, and surface perfection. To generate readily interpreted worst-case corrections, we assume that the bars' total thickness W varies randomly in the x–y plane over a range $[-b, b]$; the bars' positions in the x direction vary randomly over a range $[-g, g]$; and the bars' widths vary randomly over a range $[-c, c]$, all with associated uniform probability density functions.[5] Under a broad range of

[5] The general case based on arbitrary probability density functions is treated in Ref. [2].

circumstances, the primary effect of the variability of W will be to alter the ratio $I^{(1)}/I^{(0)}$ *by adding the terms*

$$[e^{-2\pi\langle W\rangle k}(Q_4-1)-2(Q_1-1)\cos 2\pi\langle W\rangle\delta+2Q_3\sin 2\pi\langle W\rangle\delta] \tag{21}$$

and

$$(\eta^{-1}-1)[e^{-2\pi\langle W\rangle k}(\eta^{-1}-1)(Q_4-1)+2(Q_1-1)\cos 2\pi\langle W\rangle\delta-Q_3\sin 2\pi\langle W\rangle\delta] \tag{22}$$

into, respectively, the bracketed numerator and denominator of the right side of Eq. 10. Here we have utilized the unindexed Eq. 14, represented the average bar thickness by $\langle W\rangle$, and employed shorthand symbols Q_j $(j=1,3,4)$ for

$$Q_1=\frac{k\cos 2\pi\delta b\sinh 2\pi kb+\delta\sin 2\pi\delta b\cosh 2\pi kb}{2b\pi(k^2+\delta^2)}, \tag{23}$$

$$Q_3=\frac{\delta\cos 2\pi\delta b\sinh 2\pi kb-k\sin 2\pi\delta b\cosh 2\pi kb}{2b\pi(k^2+\delta^2)}, \tag{24}$$

$$Q_4=\frac{(\cos 2\pi\delta b\sinh 2\pi kb)^2+(\sin 2\pi\delta b\cosh 2\pi kb)^2}{4b^2\pi^2(k^2+\delta^2)}. \tag{25}$$

Equations 21–25 are useful in estimating acceptable limits on both the large- and small-scale surface roughness of a sample material for use in an MSFTI experiment, particularly when prior estimates of its actual optical constants are available.

The effect of the laterally random variations is primarily to modulate the diffracted nonzero orders [1]. If we express g and c as fractional lengths of the grating period a, the ideal $I^{(1)}/I^{(0)}$ ratio in Eq. 10 is transformed into

$$\frac{I^{(1)}}{I^{(0)}}\rightarrow\left(\frac{I^{(1)}}{I^{(0)}}\right)\left[\operatorname{sinc}^2\left(\frac{2g}{a}\right)\operatorname{sinc}^2\left(\frac{c}{a}\right)\right]. \tag{26}$$

The sinc^2 factors can be used to estimate acceptable limits on the lateral mechanical distortions that will be present, to a greater or lesser degree, in all sample grating structures. Conversely, accurate characterizations of the

lateral distortions of a sample grating can be used to correct the measured intensity ratios.

The final important departure from ideality that should be taken into account is the effect of nonrectangular bar edges. The issues to be covered in a comprehensive treatment are detailed, covering a wide range of cases and assumptions [2], and we must consequently restrict ourselves here to the brief derivation of an approximate worst-case criterion. We first assign a length parameter Δ_E to the grating structure in the x direction, which we center on the nominally ideal edge locations of each bar. We then assume that over the extent of this length, each edge can assume an arbitrary thickness profile, and we represent the effect of its shape by adding the decremental electric field profile transmitted through it to the ideal field distribution in the sample plane. This procedure generates two periodic field distributions, one associated with each set of (imperfect) edges of the grating bars. Clearly, as $\Delta_E \to 0$, the ideal field distribution is recovered. We now assume that each edge-transmitted field has twice the amplitude of the field transmitted by the ideal bars. Next, we appeal to elementary diffraction theory [19] and Eq. 10 to postulate that the angular spread of the edge spectra in the far field will be greater than the primary spectral spread by the approximate factor Δ_E/d. In this picture, the field amplitude transmitted by the ideal grating is taken to be proportional to $[d+(a-d)\exp(-2\pi Wk)]$ and the corresponding amplitude from the edges to $[2\Delta_E \exp(-\pi Wk)]$. A factor describing the worst-case relative intensity perturbation of, say, the first order can then be approximated by the expression

$$\left(\frac{2\Delta_E e^{-\pi Wk}(\Delta_E/d)+[d+(a-d)e^{-2\pi Wk}]}{[d+(a-d)e^{-2\pi Wk}]}\right)^2. \tag{27}$$

Assuming the representative conditions $2\pi Wk \simeq 1$ and $a \simeq 2d$, we find the perturbation on the first order to be given approximately by $[4\Delta^2{}_E/(d^2(1+\sqrt{e}))]$, and assuming (again as a worst case) an equal perturbation of the zeroth order, we arrive at a maximal perturbation on the unindexed ratio R (defined by Eq. 11) of

$$\Delta R \simeq 3\left(\frac{\Delta_E}{d}\right)^2. \tag{28}$$

Perhaps the most important practical implication of Eq. 28 is that real-life experimental grating bars in the MSFTI technique should be chosen with

aspect ratios $(a-d)/W$ as large as possible, since for most fabrication techniques this will be naturally conducive to the minimization of Δ_E/d.

V A CHARACTERIZATION OF THE OPTICAL CONSTANTS OF Au USING MSFTI IN THE 280–640 eV RANGE

In this section we will augment the predominantly theoretical discussions of the prior sections by briefly reviewing the implementation and results of an actual MSFTI experiment performed on Au [3] in the 280–640 eV range.

The radiation source employed for the experiment was a bending magnet on SPEAR,[6] the storage ring at the Stanford Synchrotron Radiation Laboratory (SSRL) [42]. The radiation, which is characterized by a broad and smooth spectrum [43], was monochromatized with a 1m Rowland-circle monochromator, whose details and performance characteristics are described elsewhere [44]. For our present purposes we require the fact that this single-grating instrument, when tuned to a given photon energy, is also capable of transmitting the higher diffracted orders of shorter-wavelength radiation emanating from a broadband source.

The sample gratings for the experiment were fabricated at IBM's Thomas J. Watson Research Center, using combinations of wet and dry etching and vacuum deposition techniques. Several of the technical aspects and developments associated with this work have been described in the literature [45]. In particular, in view of the generation of the initial grating pattern as a holographic interferogram, the grating period a is defined with exceptional precision. A micrograph of a typical sample grating is shown in Fig. 4. As can be seen, the grating bars are supported on a grid structure constituted of much thicker bars, and that support grid is itself supported on a tertiary grid (not shown) with proportionately coarser features. Apart from the micrographs, which were taken *following* the MSFTI experiment, the gratings' dimensional parameters were initially characterized with an inverse application of the formulas in Section IV. To wit, a set of values of δ and k was selected in the 100–160 eV range that had earlier been found to corroborate the measured performance of other well-characterized Au gratings at SSRL [46, 47], and applied to unfold d and W from the measured intensity ratios R. The basic parameters of the final set of three gratings selected to measure $\hat{n}$ are listed in Table II. To be noted are the fairly high values of $(a-d)/W$, stipulated by the analytical results of Section IV.

[6] Stanford Positron Electron Asymmetric Ring.

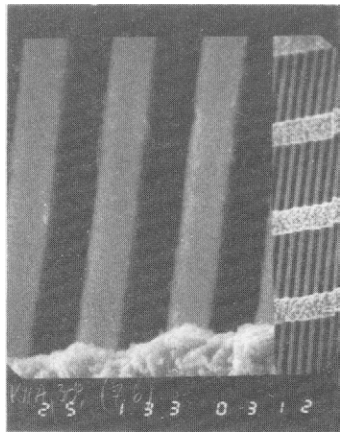

Fig. 4. Electromicrograph of an Au sample grating structure used in an initial version of an MSFTI experiment. The period of the free-standing bars is 2.5 μ and their width-to-thickness ratio $(a-d)/W$ is approximately 10. Portions of the supporting structure for the sample bars are visible in the demagnified structure on the right. During the experiment, the support structures face the source and intercept a significant fraction of the probe light.

A typical MSFTI spectrum, drawn from the prior characterization of the gratings' dimensions, is shown in Fig. 5. The profile reveals both spectral and line-shape anomalies, both of which typify the kinds of systematic errors that can arise in an actual experiment. In the example shown, the anomalous peaks between the zeroth and first orders stem from the harmonics transmitted by the monochromator, and it is apparent that the spectral components with which they are associated contribute to both the zeroth and first orders of the primary spectrum. The peak shape distortions are related to the shadowing effects of the structural grids sup-

TABLE II

Selected Parameters of Sample Au Gratings Used in an MSFTI Experiment

Grating	W (Å)	d/a	a (μm)
K12A[a]	969.5	0.312	2.5
13F[a]	1774.6	0.565	2.5
K4[a]	1067.0	0.350	2.5

[a] Grating identification codes.

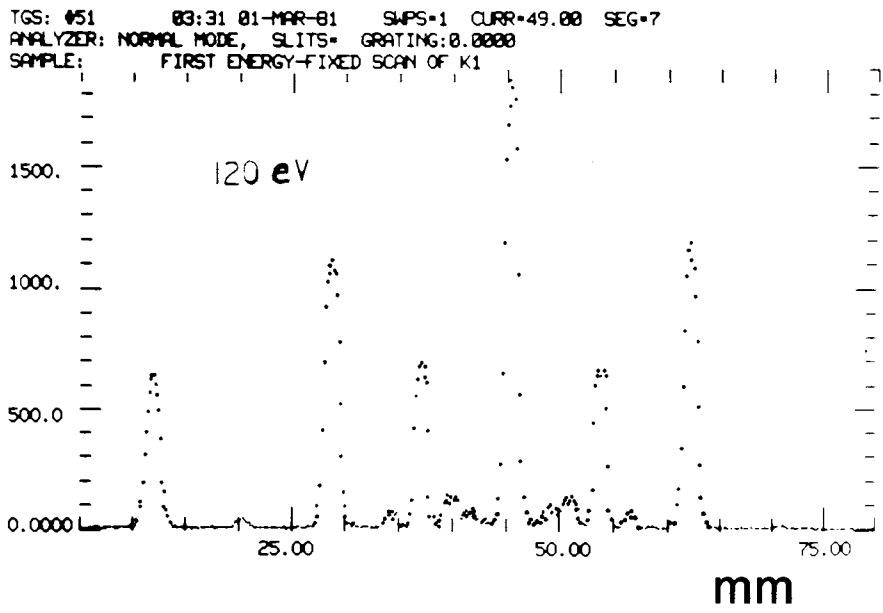

Fig. 5. Experimental transmission diffraction spectrum generated by an Au sample grating structure. The source radiation is monochromatized synchrotron light from a bending magnet. The 120 eV first and negative first orders are located at 28 mm and 62.5 mm.

porting the grating bars, and the slight asymmetry in the peak values is traceable in part to misalignments in detector motion [2].

Following measurements of the diffracted spectra, the data were analyzed and corrected for systematic errors, including those associated with the imperfections of the grating structures and their support grids, and the values of δ and k were generated as described in Section IV. Particularly troublesome was the task of numerically separating the spectra of interest from the anomalous higher-energy diffraction patterns, which are themselves model-dependent. In all these calculations the sensitivity expressions (Eqs. 16–19) were utilized to converge on self-consistent values of $\hat{n}$ among the three sets of grating pairs, and to estimate the final error limits. A set of sensitivity curves based on the final computed constants for one of the gratings is displayed in Fig. 6. Above 640 eV and below 280 eV, the curves are smoothly adjusted to optical constants reported elsewhere [32]. The final experimental values of δ and k are listed in the fourth and sixth columns of Table III.

A brief assessment of the displayed constants is in order. In the literature, Au has been particularly noted for the significant variation in the values of both its measured and calculated constants [48, 49]. These discrepancies have been associated with the apparently wide variability in the physical parameters of thin gold films prepared via different techniques

[50], or with postulated physical differences between the surface and interior regions of ordinary samples [51]. In view of these considerations, it is of interest to contrast the MSFTI constants with those measured or derived by alternative techniques.

In the fifth and seventh columns of Table III we have listed the corresponding optical constants for Au compiled by Henke *et al.* [23]. These values, based on first-principle calculations fitted to available (and very sparse) experimental data, can be used as an arbitrary referent for our purposes. We note fairly good agreement for k, with the exception of 640 eV and the 280–360 eV interval. Regarding these discrepancies, partial corroboration is available for the MSFTI results in the theoretical *atomic* absorption cross-sections compiled by Plechaty, Cullen, and Howerton [52], who identify strong resonances both at $\simeq$320 eV and 600 eV, the latter being clearly associated with Au's N edge. A corresponding interpretation for the large discrepancy with Henke's δ, however, which is based largely on Kramers–Kronig analysis of the absorption data, has proved elusive. The technique most closely related to MSFTI in terms of sample penetration, that of thin-film absorption, has been utilized by Hagemann, Gudat, and Kunz [32] to measure k for Au over this region. Their films were prepared by evaporation from resistance-heated crucibles onto mesh-supported polymer substrates, which were subsequently etched away outside of the vacuum. Their measured k values, interpolated, agree with both Henke's and MSFTI's to within the cited error bounds. Their primary

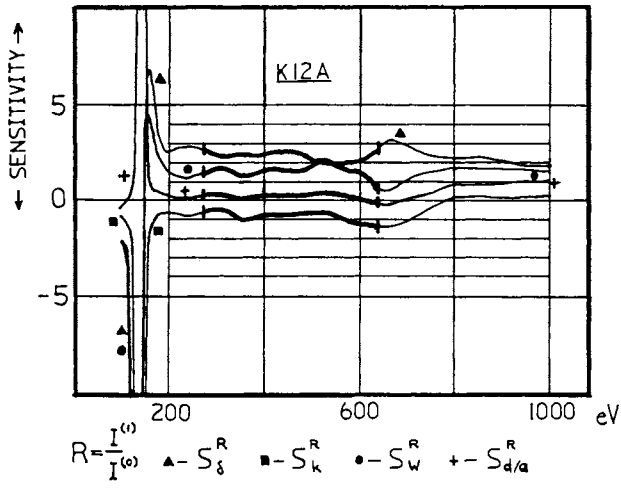

Fig. 6. Sensitivity curves for a typical sample grating (code number K12A) used to measure optical constants via MSFTI. Bold curve segments denote the 280–640 eV measurement interval. For this particular grating, the diffracted order ratio R is seen to be minimally sensitive to the aperture-to-period ratio d/a.

TABLE III

Optical Constants of Gold (Au) as Determined by the MSFTI Method and by Henke *et al.* [23].

eV	cm^{-1}	μm	$1-n$ (MSFTI)	$1-n$ (Henke)	k (MSFTI)	k (Henke)
280	—	0.00443	0.0119	0.00732	0.00762	0.101

560	—	0.00241	0.00648	0.00430	0.00378	0.00361
600	—	0.00207	0.00596	0.00385	0.00329	0.00328
640	—	0.00194	0.00500	0.00365	0.00463	0.00294

The average error bounds for the MSFTI values, dominated in large part by systematic errors, are estimated to be about ±18% for k and ±10% for δ ($\delta \equiv 1-n$).

data points, however, are too sparse for resolving the two absorption anomalies observed with MSFTI. With respect to δ, Hagemann *et al.*'s Kramers–Kronig analysis produces values that are closer to MSFTI's than to Henke *et al.*'s in the 280–400 eV range, but closer to Henke *et al.*'s from 400–640 eV. A set of characterizations of δ and k for Au based on multiple-reflectivity measurements in the soft X-ray range has recently been reported by Windt *et al.* [53]. Their sample surfaces were prepared by *e*-beam evaporation of Au onto polished Si wafers, and their measurements extended up to ≈520 eV, with only three data points reported in the 280–520 eV interval. Their k value of 0.0042 at 385 eV is noticeably lower than in all the previous compilations cited, and their δ values of 0.0069 at 280 eV and 0.00418 at 385 eV are also significantly lower than Henke *et al.*'s. On the other hand, their values compare, by and large, favorably with Lukirskii *et al.* [51], who also employed a reflectivity-based technique (at virtually the same three energy points) in an experiment reported in 1964. In still other compilations reviewed for this chapter, for example, Zombeck [54], data for the 280–640 eV range are either drawn from some of the above sources or generally fall within the same range of values.

This wide-ranging spectrum of results clearly underscores the still-unsettled status of current experimental knowledge of the optical constants of Au in the soft X-ray range, and of their systematic relationship to the surface or bulk properties of samples. Whereas some degree of correlation is perhaps apparent among the *measured* constants acquired with reflection- versus transmission-dependent techniques, the sparseness of actual measurements of *both* components of $\hat{n}$, by whatever technique, is clearly still too inhibitive to permit reliable conclusions to be drawn. This

state of affairs is no doubt partially due to the enhanced difficulty of optical experimentation in ultra-high vacuum, and to the still-extant lack of instrumentation comparable in quality or sophistication to that available in other spectral regions. In this respect, the development of a technique such as MSFTI, which is both experimentally simple and can measure both δ and k directly with optimal sensitivity, could prove essential in helping to identify and resolve the issues involved.

VI PROBLEMS AND PROSPECTS IN SAMPLE PREPARATION

Perhaps the most pertinent question that can be raised at this point concerning the present and future utility of multiple-slit Fourier transform interferometry is whether high-quality samples constructed out of materials other than Au can be prepared. It is clear that the long-term import of this metrological technique will depend directly on its ability to accommodate a wide variety of elements and materials, enabling intercomparisons and correlations with data taken by other methods.

From our present perspective, we can remark that the preparation of samples of the type used in the first experiments, namely, free-standing, grid-supported diffraction gratings, out of a wide variety of materials other than Au, does not appear overly promising. This is due in large part to the complexity of the associated fabrication processes [37, 45], which utilize sequences of several in- and out-of-vacuum procedures of both a chemical and mechanical nature. Thus, the quality and integrity of the bars in the final grating structure can strongly depend on the chemical and mechanical properties of the element or material being used, necessitating the programmatic exploration of various fabrication procedures for virtually each material of interest. To date, for example, successful results have been reported for Ag [55], whereas preliminary attempts with Ni and Cu have been inconclusive [56].

Based on this state of affairs, it seems apparent that samples of less complex construction must be made amenable to the MSFTI technique if it is to become widely applied. To this end, we can consider two simpler alternatives. First, we consider the structure in Fig. 7a [57]. Its preparation is based on the deposition of a thin film onto a substrate, and a subsequent inscription of a periodic groove structure into its surface. Due to the mechanical support of the substrate and the reduced number of fabrication steps, it can be expected that a much larger class of materials could be prepared for MSFTI in this way. Indeed, this expectation is corroborated by ongoing work in associated areas of microfabrication technology [58]. We note that the analytical formalism developed in this chapter is entirely

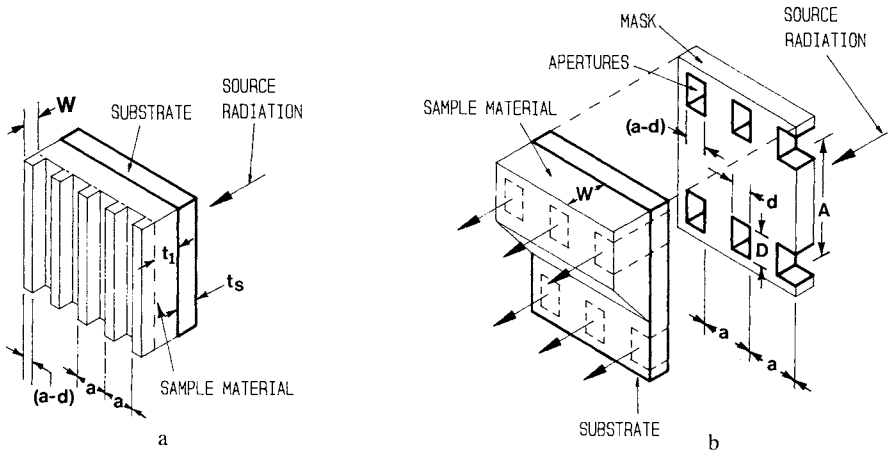

Fig. 7. Two alternative sample configurations (a and b) for probing the optical constants of a wide range of metallic and nonmetallic thin films in the soft X-ray range with the technique of MSFTI. The essential notion behind both configurations is to bypass the potentially problematical fabrication of free-standing diffraction gratings out of unsuitable materials. In configuration b, all microfabrication or micromachining of the sample material can in principle be avoided.

applicable to the depicted configuration, since the plane-parallel substrate (thickness t_s) and subsequent sample slab (thickness t_1) modulate the probe wavefronts homogeneously. Experimentally, the configuration is superior in avoiding the systematic errors introduced by a support grid; on the other hand, it will in general place significantly higher demands on the intensity of the radiation source.

An alternative technique that would demand an even greater source intensity, but that would in principle allow the MSFTI characterization of any material that can be deposited in thin-film form—and this includes most of the elements—is shown in Fig. 7b. Here the periodic sample bars are defined by a sequence of channels of width $a-d$ and height D cut or etched into an opaque mask; the apertures are defined by a second sequence of width d located at a distance A below. A must be chosen large enough to occlude the edge region of the thin film to ensure the homogeneity of both the defined bars and apertures. During operation, the mask is adjoined to the substrate and the two grating structures are defined (in the eikonal approximation) by the radiation passing through the apertures. With regard to the viability of this approach, we note that Si structures such as the depicted mask have recently been implemented, with smoothnesses approaching the *atomic* level [59]. This suggests that spectra of the highest quality could be generated with such configurations. Feasibility studies of sample preparation using this approach, as well as the develop-

ment of the analytical formalism for the mask/thin-film geometry, which in certain respects differs from that outlined in Sections I and IV, are currently in progress.

VII PROSPECTS FOR MSFTI IN OTHER SPECTRAL REGIMES

It is of interest to inquire into the applicability of MSFTI in spectral regimes outside of the VUV/soft X-ray range. Just as in the comparisons drawn in Section II, the central issue is whether alternative techniques can produce superior results, and at what cost. As a specific example, consider the sensitivities defined in Section IV (Eqs. 16–18), in the limits $r \to 0$ and $W \to 0$. These become $[1+(k/\delta)^2]^{-1}$, $[1+(\delta/k)^2]^{-1}$, and $\{1+[1+(k/\delta)^2]^{-1}\}$, respectively. As opposed to the corresponding sensitivities of a split-beam interferometer, they are all seen to be independent of W. Thus, in regions where k is of the same order of magnitude as δ, and where surface phase-shift and reflectivity effects can be accounted for, MSFTI would appear to offer advantages for the testing of even extremely thin films in transmission. Based on existing tabulations of k and δ [60–62], we can consequently infer that this form of MSFTI could in principle be applied to a significant number of materials in regions of the IR–visible–UV range. A practical factor that could enhance the applicability of MSFTI at these lower energies is the ready selection of focusing and collimating optics (namely, lenses), the judicious use of which would permit significantly shorter source/sample/detector lengths and coarser gratings. Such structures could consequently be imbued with higher quality, enhancing the experimental reliability even further. On the other hand, in cases where only δ was required, ordinary split-beam interferometry, or even the FTI scheme employed by Rayleigh, would probably remain preferable, since—as was discussed earlier—the simpler sample structures and the ready availability of highly intense and tunable coherent photon sources in the lower energy regimes would more than compensate for their relative inefficiency.

At energies well in excess of 3–5 KeV, the natural crystal structures of most materials begin imposing their own modulation on the light transmitted into the far-field (via Bragg or Laue diffraction), and numerous higher-energy scattering mechanisms (for example, Compton) start manifesting themselves [63]. In view of this, the additional modulation of a high-energy diffraction pattern by an array of bars of the material in question might not necessarily prove to be of value. One possibly useful interpretation of MSFTI in this regime would be to view the individual atomic planes as the "bars" of a grating, and the interplane spacings (with their lower electron densities) as the "apertures". Such a configuration could conceivably be

employed to help characterize inner-shell scattering coefficients at the appropriate absorption edges in the 10 KeV–1 MeV range, and even of nuclear cross-sections at absorption edges in the 100 KeV+ energy domain. Although the quality, alignment, and photon flux requirements for a sample structure of this type would evidently be severe, recent technological developments have shown that both of these requirements could in fact be duly met [64, 65].

A final question, of possible importance at sub-VUV energies, is whether MSFTI configurations based on reflection could be implemented. A general assessment of the analytical formalism of MSFTI clearly shows that this would indeed be possible. On the other hand, configurational problems such as the copositioning of a reference interference pattern, or the variation of the incidence and reflection angles to establish multiple equations in δ and k (when only one material is being used), would seem to imply a considerably higher degree of experimental complexity. In view of the complicated dependence of the reflectivity on $\hat{n}$ (see the discussion in Sections I and IV), the analytical complexity of the experimental equations could in general be expected to be greater as well. As in all proposed applications of MSFTI (reflection- or transmission-based), the bottom-line question of whether the anticipated complexity is justified for a given material would need to be answered with a careful case-by-case analysis of the attainable precision in comparison to alternative techniques.

SUMMARY VIII

The VUV/soft X-ray range is currently perhaps the least developed in terms of versatile coherence techniques and a broad range of sophisticated optical instrumentation. An inhibiting factor to progress in these two areas has undoubtedly been our limited knowledge and understanding of the optical constants of candidate materials. In this chapter we have reviewed MSFTI, a method for determining optical constants that is based on the interference of multiple diffracted beams following transmission. It was shown to feature a number of advantages for characterizing the complex index of refraction $\hat{n}$ of thin films in the 0.1–3 KeV range; in particular, certain troublesome errors associated with alternative techniques in this region can be minimized or avoided. In broad terms, the technique has been made possible only recently due to significant advances in high-brightness, soft X-ray sources and the advent of reliable microfabrication technology. With additional directed development of these two resources, such as was outlined in Section VI, it is expected that the method could eventually be made applicable to a wide variety of materials, enabling the

programmatic characterization of their optical constants in thin-film form. Such an experimental program would provide data complementary to that acquired with reflectivity-based techniques, enabling us, perhaps for the first time, to begin systematizing our knowledge and understanding of $\hat{n}$ in the soft X-ray range.

ACKNOWLEDGMENTS

The author would like to acknowledge critical support from Elisabeth Källne, Ingolf Lindau, and Eberhard Spiller during the initial experimental implementations of the MSFTI technique. The tabulated optical constants were characterized at the Stanford Synchrotron Radiation Laboratory (SSRL), which is operated by the Department of Energy, Office of Basic Energy Research, Division of Chemical Sciences. That office's Division of Materials Science is acknowledged for support for this undertaking.

INTRODUCTION I

Although optical constants ordinarily are determined by measuring the primary interaction of photons with matter, we describe here a method that relies on the measurement of a secondary process, namely photoemission. The determination of the total photoelectric yield as a function of the angle of incidence on a mirror made of a conducting material, or of a thin film of such a material on a well-defined substrate, is sufficiently specific to obtain accurate optical constants. Pepper [1] has given a simple but very successful model, which yields an analytic expression for the photoelectric yield of a bulk conductor and also of a thin conducting film on a substrate if the optical constants of the materials involved, the film thickness, and the average escape depth of the photoelectrons are known. This model is based on the description of photoemission as a four-step process: primary excitation, multiplication by inelastic scattering, migration to the surface,

ISBN 0-12-544422-2

and penetration through the surface into the vacuum. The factor that describes the penetration of photoelectrons through the surface barrier and some other constant factors cancel out if only the relative photoelectric yield for different angles of incidence is of interest. This model can be used in reverse to fit experimental angular-dependent, photoelectric-yield measurements and to determine optical constants, film thickness, and electron escape depth as fitting parameters.

Although the method is applicable only at photon energies above the photoemission threshold, no limitations other than practical ones appear to exist for higher photon energies. This method gives excellent results in those cases that have been investigated up to now. It was originally applied by Arakawa *et al.* [2, 3] with the primary interest of obtaining electron escape depths of Al at 21.1 eV and of C at 20–64 eV photon energy. In addition, the real part of the index of refraction was obtained. There are also some other investigations based on Pepper's [1] and similar formalisms [4]. In combination with synchrotron radiation, the method was explored thoroughly by Birken *et al.* [5] with Al films evaporated in ultra-high vacuum. In this case, a measurement of multiangle reflectances was performed on the same films without breaking the vacuum. Both methods yielded optical constants in excellent agreement with each other. The method was extended later at the HASYLAB reflectometer [7, 8] to copper, platinum, and Kanigen, a nickel alloy used as a polishable mirror material. Some of these unpublished results are included in this chapter. In Section II, the theoretical background is presented in detail, then the fairly simple experimental setup is described in Section III, taking as a model case the arrangement as it was used at HASYLAB. Section IV gives the examples, and finally, Section V points out future prospects of the method.

II THEORETICAL BACKGROUND

We consider a linearly polarized light wave incident on a film of thickness d, which is supported by a substrate. The angle of incidence is measured relative to the normal to the film surface, and the optical properties of the film (1) and the substrate (2) are characterized by the complex dielectric functions ε_1 and ε_2, respectively, Fig. 1. ε is related to the complex index of refraction by $N = n + i\kappa = \sqrt{\varepsilon}$. The central assumption in describing the photoelectric yield is that the contribution of an infinitesimal volume element of the film to the total number of escaping electrons is proportional to the photon energy absorbed within that volume element. The electromagnetic-field distribution inside the film is thus responsible for the primary excitation of photoelectrons. On the other hand, the dielectric functions ε_1 and ε_2, together with the boundary conditions, determine this field.

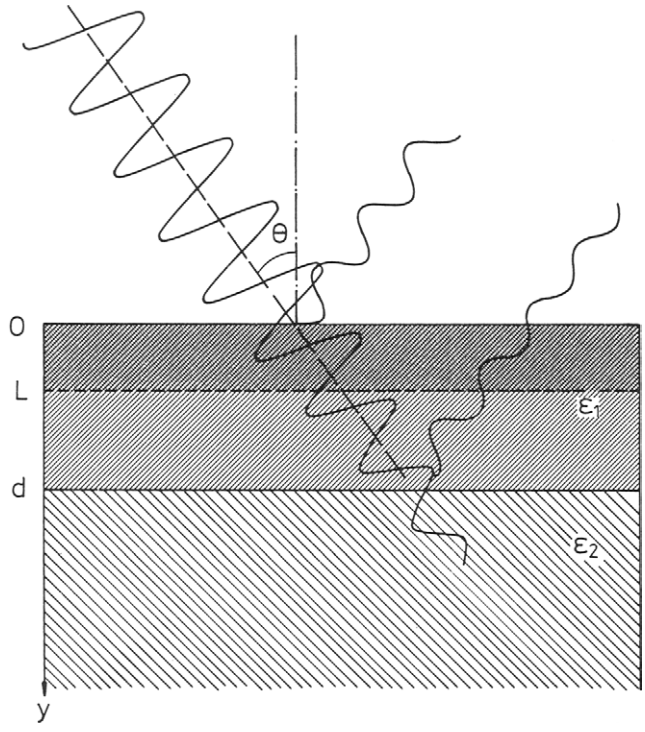

Fig. 1. Schematic representation of the optical system composed of a film (1) with thickness d, which is supported by a substrate (2). θ is the angle of incidence of the incoming light beam, and $\varepsilon_{1,2}$ denote the dielectric functions of the film and the substrate, respectively. The vacuum dielectric function ε_0 is unity. L is the mean electron escape length.

In calculating the photoelectric yield, diffusion of the primarily excited photoelectron to the surface, multiplication due to electron–electron scattering along its path, and escape through the surface potential barrier are all condensed in the simple function $Ce^{-y/L}$. The factor C takes into account the multiplication of the primary electron through electron–electron scattering and the probability of penetration through the surface potential barrier for the secondary electrons. $L(\hbar\omega)$ denotes the photon-energy-dependent electron escape depth. This is a complicated function of the mean-free paths for both elastic electron–phonon and inelastic electron–electron scattering averaged over the whole spectrum of kinetic energies. The introduction of such an exponential escape function is a simple approximation, which cannot be expected to describe perfectly this intricate escape and multiplication mechanism. Nevertheless, for our present application it turns out to be adequate.

If the contribution of the substrate to the total yield is negligible, that is,

$L \ll d$, the expression for the total yield may be written as

$$Y = C \int_0^d e^{-y/L} \eta(y)\, dy = CF(L), \tag{1}$$

where $\eta(y)$ is the volume absorptance, which is proportional to the negative divergence of the Poynting vector. This approximation, however, is no longer applicable if the film thickness becomes comparable to the electron escape depth, since then the photoelectrons arising from the substrate region must also be taken into account. This holds even in the case where the substrate is an insulating material. For electrons excited within the substrate, an analogous escape probability function $C_s e^{-y/Ls}$ may be assumed, but the values of C_s and L_s might be very different from those pertaining to the film. Within the frame of this chapter, we do not wish to expand Pepper's model further for such a case. In principle, however, this appears to be possible with the disadvantage that electron escape will require two (or more) additional parameters.

Defining the quantity $G(\theta) = Y(\theta)/Y(0)$ as the relative angular-dependent total yield and neglecting electrons from the substrate, the factor C cancels out, since it does not depend on the angle of incidence θ of the incoming photons. Pepper has calculated analytic expressions for the absorption of energy per unit volume as well as for the reflectance and the transmittance for a system, which is composed of a film on a substrate [1]. The film and the substrate are allowed to be absorbing, homogeneous, and uniaxially anisotropic media, with their optical axes in the direction normal to the boundaries. Here, Pepper's equations for the case of a film on a substrate with homogeneous, isotropic, optical properties are reproduced for completeness:

$$\begin{aligned}
F_s(L) = {} & \frac{(1-|r_{1,s}|^2)\alpha}{|1+r_{1,s}\exp(2id\xi_1)|^2}\left\{\frac{1-\exp(-(\alpha+1/L)d)}{\alpha+1/L}\right. \\
& + |r_{2,s}|^2 \exp(-2\alpha d)\frac{1-\exp(-(1/L-\alpha)d)}{1/L-\alpha} \\
& \left. + 2\exp(-\alpha d)\,\mathrm{Re}\left[\frac{r_{2,s}(\exp(2i\xi_1' d)-\exp(-d/L))}{2i\xi_1'+1/L}\right]\right\} \\
F_p(L) = {} & \frac{(1-|r_{1,p}|^2)\alpha}{|1+r_{1,p}r_{2,p}\exp(2id\xi_1)|^2}\left\{\frac{1-\exp(-(\alpha+1/L)d)}{\alpha+1/L}\right. \\
& + |r_{2,p}|^2 \exp(-2\alpha d)\frac{1-\exp(-(1/L-\alpha)d)}{1/L-\alpha} \\
& \left. + 2\exp(-\alpha d)\,\mathrm{Re}\left[\frac{r_{2,p}(\exp(2i\xi_1' d)-\exp(-d/L))}{2i\xi_1'+1/L}\right]\frac{\xi_1'\,\mathrm{Im}(\varepsilon_1^*\xi_1)}{\xi_1''\,\mathrm{Re}(\varepsilon_1^*\xi_1)}\right\}
\end{aligned} \tag{2}$$

$$r_{j,s}=\frac{\xi_{j-1}-\xi_j}{\xi_{j-1}+\xi_j}, \qquad r_{j,p}=\frac{\varepsilon_j\xi_{j-1}-\varepsilon_{j-1}\xi_j}{\varepsilon_j\xi_{j-1}+\varepsilon_{j-1}\xi_j}, \qquad (j=1,2),$$

where $\xi_j=2\pi/\lambda\sqrt{\varepsilon_j-\sin^2\theta}(j=0,1,2)$ are the y components of the wave vector within the three media. The indices s and p refer to incident light with s- and p-polarization, respectively, and $r_j(j=1,2)$ are the Fresnel amplitude reflectance coefficients of the two boundaries. ξ_1' and ξ''_1 are abbreviations for the real and imaginary parts of ξ_1, respectively, and * denotes complex conjugate. The quantity $\alpha=2\xi''_1$ is the effective absorption coefficient of the film that depends on the angle of incidence. If the film thickness approaches infinity, these equations reduce to those which describe the relative total yield from a bulk system:

$$F_i(L)=(1-|r_{1,i}|^2)\frac{\alpha}{\alpha+1/L}, \qquad (i=s,p). \tag{3}$$

Eqs. 2 and 3 may be used in a least-squares-fit procedure in order to determine the optical constants, film thickness, and the electron escape depth. Therefore, a χ^2 function

$$\chi^2=\sum_{i=1}^{n}\frac{1}{\sigma_i^2}[G_{\text{exp}}(\theta_i)-G_{\text{theo}}(\theta_i,\varepsilon_1,\varepsilon_2,d,L)]^2, \tag{4}$$

has to be minimized, while the optical constants, the film thickness, and the escape depth serve as fit parameters. σ_i denotes the statistical error of each experimental point.

In the following, the sensitivity of $G(\theta)$ spectra to changes in $\varepsilon=\varepsilon'+i\varepsilon''$ is analyzed. Since by definition $G=1$ at normal incidence, the information on $\varepsilon=\varepsilon'+i\varepsilon''$ is contained mainly in the angular region around the critical angle of incidence of the material under investigation. In the XUV spectral range, the values $|1-\varepsilon'|$ and ε'' typically are less than 0.1 for many materials. Critical angles therefore are close to $\theta=90°$, mostly above $\theta=80°$. The individual shapes of the $G(\theta)$ spectra are due to two competing mechanisms:

(1) Since $n<1$, the penetrating wave is always refracted away from the surface normal. At the critical angle $\theta=\theta_c$, the refracted wave propagates parallel to the surface, and the power deposited in the material is concentrated in a small layer below the surface. Consequently, the total yield is

much higher than at normal incidence, where the energy is deposited in deeper regions of the sample.

(2) As the angle of incidence is further increased, the energy flux into the sample decreases at the expense of the increasing reflectance of the sample, which is unity at $\theta = 90°$. Thus, as θ approaches 90°, the total yield vanishes. The shape of the $G(\theta)$ curve is mainly determined by ε'', whereas the position of the maximum in $G(\theta)$ yields information predominantly on ε'.

The left upper part of Fig. 2 shows calculated $G(\theta)$ spectra between 60° and 90° angles of incidence for three different values of ratio L/λ and *s*-polarized light. The arrows indicate the maximum of each $G(\theta)$ curve.

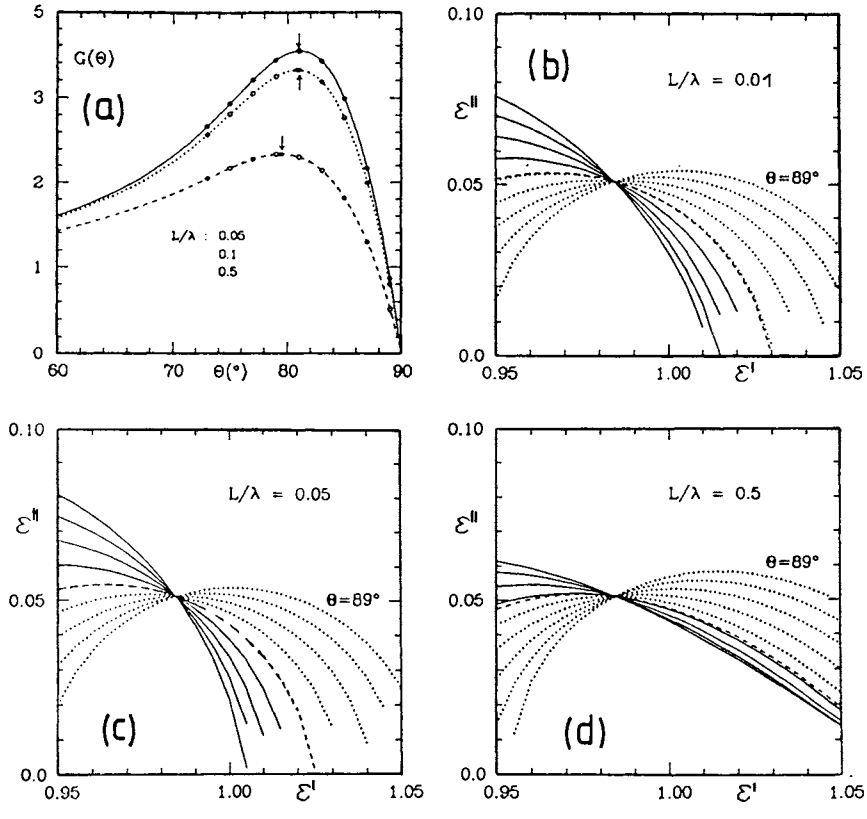

Fig. 2. Calculated relative angular-dependent total photoelectron yield from a bulk system for three different ratios L/λ (a) and curves of constant $G(\theta)$ (b, c, d), corresponding to the $G(\theta)$ points in (a) as marked by circles. The dashed curves of constant $G(\theta)$ in (b, c, d) correspond to the maxima of the $G(\theta)$ spectra in (a). Consecutive curves of constant $G(\theta)$ differ from each other by $\Delta\theta = -2°$.

Also plotted in Fig. 2 are curves of constant $G(\theta)$ within the complex-ε plane corresponding to the marked points on the angular-dependent $G(\theta)$ curves. Consecutive curves of constant $G(\theta)$ differ from each other by $\Delta\theta = -2°$, and the dashed lines correspond to the points at the maximum of the $G(\theta)$ curves. In principle, the point of intersection of two curves of constant $G(\theta)$ determines a value for $\varepsilon = \varepsilon' + i\varepsilon''$. An indication of the sensitivity of $G(\theta)$ spectra to changes in ε is the angle of intersection of the curves of constant $G(\theta)$. Usually the $G(\theta)$ values have an uncertainty due to experimental errors. As a consequence, the curves of constant $G(\theta)$ will be shifted parallel to themselves by an amount that depends on the magnitude as well as on the sign of the error. From this it follows that the uncertainty of the value of ε determined from $G(\theta)$ spectra increases with decreasing angle of intersection of different curves of constant $G(\theta)$. As long as the wavelength λ is much larger than the electron escape depth $L(\hbar\omega)$, the curves fan out equally on both sides of the critical angle. If the wavelength becomes comparable to the electron escape depth or smaller, the curves of constant $G(\theta)$ for angles smaller than the critical angle are less separated than those for larger angles of incidence. In this case, the decrease of $G(\theta)$ above the critical angle of incidence, which originates from the loss of penetrating intensity due to the increasing reflectance, is decisive in determining the optical constants. Although surface roughness strongly influences reflectance measurements, its influence on total-yield measurements may be less important. This conjecture stems from the fact that in the case of not-too-large surface roughness and a large correlation length of the roughness profile, the sum of the specularly and diffusely reflected light is practically equal to the specularly reflected light from the corresponding perfectly smooth sample [6].

EXPERIMENTAL DETAILS III

The principle of the setup of a sample holder for measuring angular-dependent total yield is shown in Fig. 3. The sample, either a film prepared on a substrate or a bulk material, is mounted (electrically insulated) on a holder, which allows precise rotations around an axis that lies in the surface of the sample. An anode, which is fixed to the sample holder and has slits for the incoming and reflected radiation, surrounds the sample. In this way, the anode is moved rigidly with the rotating sample, and the collection efficiency for the photoelectrons is independent of the angle of rotation. A potential difference of 15 V between the anode and the photoemitter has been shown to suffice to extract practically all photoelectrons. Thus, the signal-to-noise ratio is kept high, although the measured currents through the samples are typically on the order of 0.1 nA or less. A

second shield is used to prevent the collection of electrons not resulting from photoemission from the sample. This setup permits total yield as well as reflectance measurements as a function of the angle of incidence of the incoming light.

The measurements described in this chapter have been performed at the UHV reflectometer at HASYLAB (DORIS II). The reflectometer [7] is equipped with 360° rotatable feedthroughs for sample and detector with rotational increments of 0.005° and an uncertainty of 0.03°. An adequate angular resolution and accuracy of the measurements is essential considering the importance of fast changes in intensity in the region around the maximum of the yield spectrum for the determination of the optical constants. In addition, the sample and the detector can be translated axially by up to 70 mm, allowing for measurements on two different samples.

An electron-beam gun and an oscillating quartz thickness monitor for *in situ* evaporation of films are installed in the reflectometer chamber. After baking, a base pressure of less than 3×10^{-8} Pa is reached. The experiment is supplied with monoenergetic radiation from the monochromator "Bumble Bee" in the energy range 40–1000 eV. More details on the monochromator can be found in Ref. [8].

IV EXAMPLES

Photoelectric-yield measurements have been performed with a 770 Å-thick Al film on borosilicate glass at 40–600 eV photon energy [5]. Fig. 4 shows a plot of the measured $G(\theta)$ curve of the Al film at 65.3 eV photon energy together with the fitted theoretical $G(\theta)$ curve. The strong interference pattern of the $G(\theta)$ curve, which allows the determination of the film

thickness d from the fit with high accuracy, is typical of photon energies below the Al–$L_{2,3}$ edge. The theoretical expression of $G(\theta)$ depends on six adjustable parameters, the optical constants ε_{Al} and the thickness d of the Al film, the optical constants ε_{Sub} of the substrate, and the electron escape depth L. Values for the optical constants of the substrate, determined from multiple-angle reflectance measurements of the substrate before evaporating the Al film, were treated as fixed fit parameters. Above the Al–$L_{2,3}$ edge, the interferences in the $G(\theta)$ spectra vanished, and the theoretical expression of $G(\theta)$ for a bulk system according to Eq. 3 was used to determine ε_{Al} and the electron escape length L of the Al film. As an example, Fig. 5 shows a plot of the measured $G(\theta)$ curve of the same sample as in Fig. 4 at 122.9 eV photon energy, together with the fitted theory. In addition, the reflectance versus angle of incidence for a large number of angles of the same Al film was measured. Fitting of these reflectance spectra to Fresnel's equations yielded values for ε_{Al} and the thickness of the Al film, and therefore enabled a direct comparison of the two methods applied to the same sample. Figures 6 and 7 summarize the fit results of ε_{Al} obtained by both the total yield and the reflectance measure-

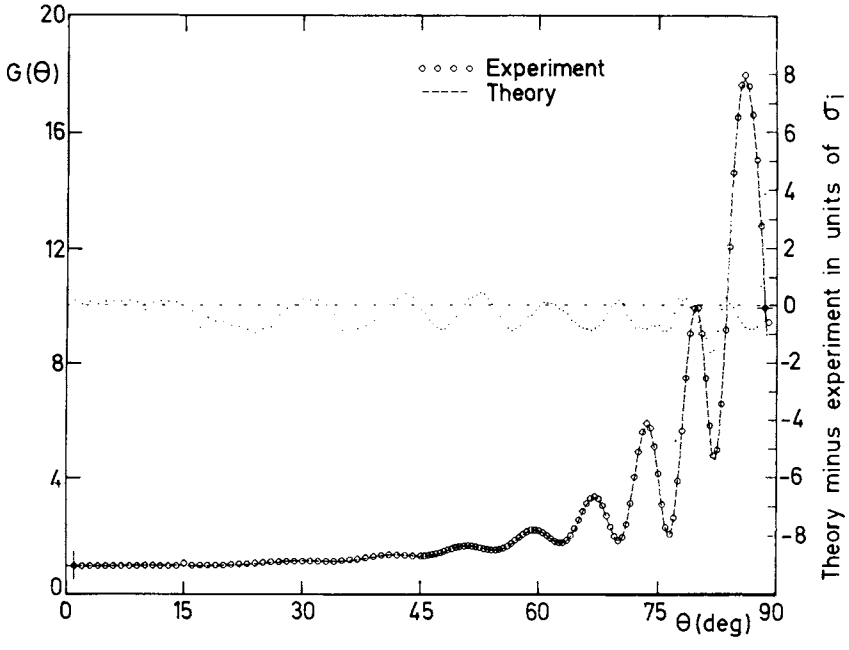

Fig. 4. Total yield versus angle of incidence normalized to the yield at normal incidence at 65.3 eV photon energy of an 770 Å-thick Al film. At this energy, strong interference patterns are visible in the $G(\theta)$ spectra. The dotted line in the middle of the figure shows the deviation of theory and experiment in units of the experimental error σ_i, which was estimated to be 1% of the experimental $G(\theta)$ value. For more details, see text.

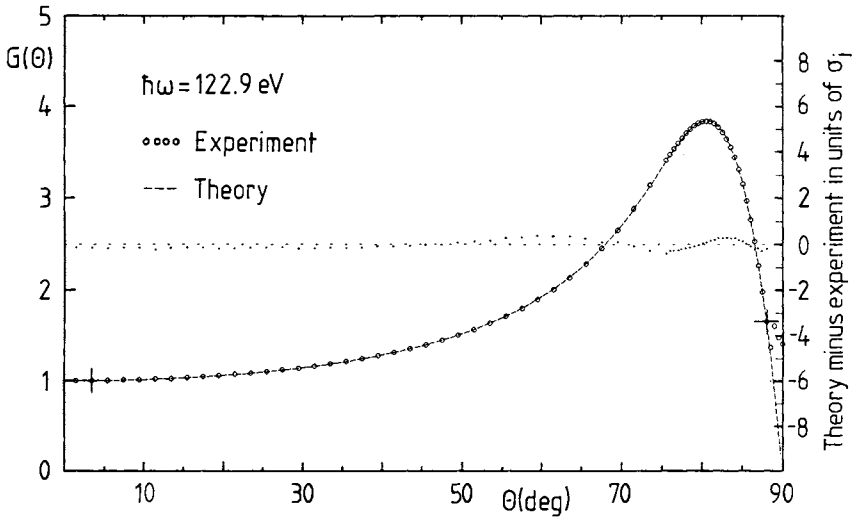

Fig. 5. Relative total photoelectric-yield $G(\theta)$ versus angle of incidence θ at $\hbar\omega = 122.9$ eV. This spectrum was obtained from the same Al film as the spectrum in Fig. 4. The fitted curve (dashed line) is based on the assumption of a bulk material, because the film appears to be opaque above the Al-$L_{2,3}$ edge.

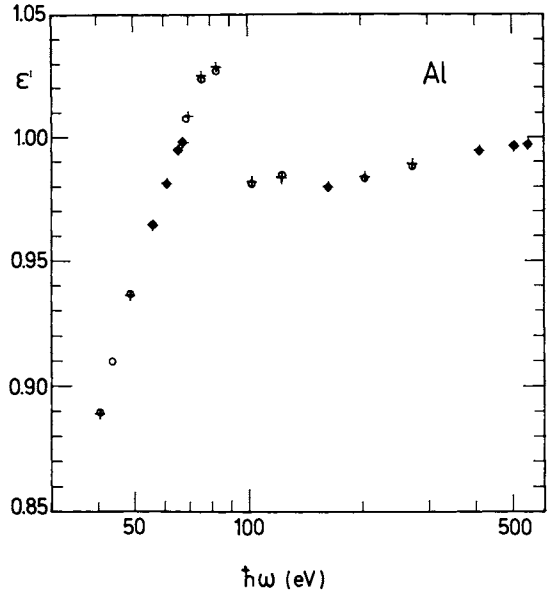

Fig. 6. Real part ε' of the dielectric function ε_{Al} versus photon energy $\hbar\omega$. The crosses denote the fit results of the total-yield method, whereas the circles refer to the reflectance measurements.

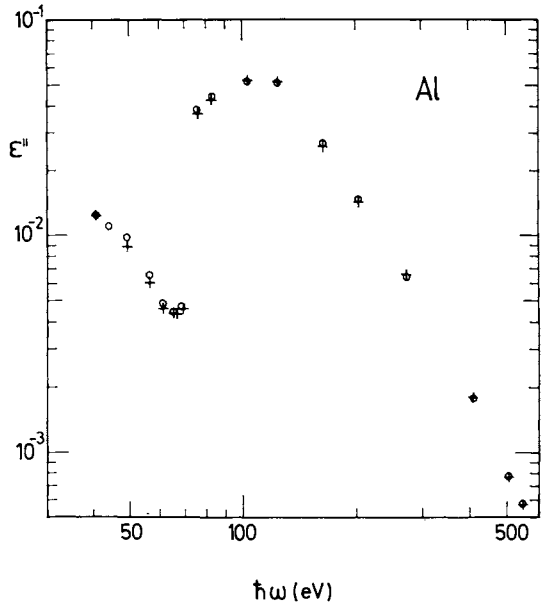

Fig. 7. Imaginary part ε'' of the dielectric function ε_{Al} versus photon energy $\hbar\omega$ (compare with Fig. 6).

ments. The value of the film thickness determined from the yield method is $d = 773 \pm 9$ Å, whereas the reflectance measurements yielded $d = 768 \pm 10$ Å. The error is determined by averaging results over a range of photon energies. The smallness of the statistical spread is an additional indication of the applicability of the whole procedure.

Similar investigations have been performed on thin copper films on glass substrates in the range of 50–900 eV [10]. An example of a measurement on Cu at 644 eV photon energy is given in Fig. 8. Figures 9 and 10 show the optical constants of two films as determined from reflectance (open symbols) and total-yield measurements (closed symbols). The thicknesses of the films have been determined to be 225 ± 5 Å (circles) and 317 ± 6 Å (diamonds) from both types of measurements. For comparison, values of ε_{Cu} have been calculated from atomic scattering factors given by Henke *et al.* [9] and are included in Figs. 9 and 10.

CONCLUSIONS AND FUTURE PROSPECTS V

In this chapter it is demonstrated that angular-dependent photoelectric yield contains sufficiently detailed information, at least in the spectral

range $\hbar\omega = 20$–1000 eV, to extract accurate values for the optical constants. Up to now the method was applied only to a few substances, all of them metals, and in most cases they were supported by a glass substrate. The measurement of a thin layer on a substrate has the advantage of producing very pronounced interference structures, by which the sensitivity of the fits appears to be considerably increased. On the other hand, a fairly powerful computer system is needed to calculate the best fit in a reasonable time. For bulk materials the mathematical procedure is much simpler.

At first glance, the method appears to be applicable only to conducting materials, including doped semiconductors. If films are used, their thicknesses have to be so large that practically no electrons emerging from the substrate penetrate the film and contribute to the yield. The reason is that such a contribution is not included in the theory, as outlined in Section II. With materials such as metals, having mean-free paths of the order of 20 Å, a film thickness on the order of 100 Å suffices. As a matter of fact, we even had good results with a 51 Å Pt film on glass [11].

Would it also be possible to measure optical constants of insulating materials in this way? It is well-known that films with thicknesses on the order of a few hundred angstroms show no serious charging problems. Actually, CsI is used above 1000 Å as a photocathode material. In this case, the problem arises from the very large mean-free paths for slow secondary electrons. Since electron–electron scattering is not possible when the kinetic energy of the electrons is less than roughly the band gap above the conduction-band minimum, only inelastic impurity scattering

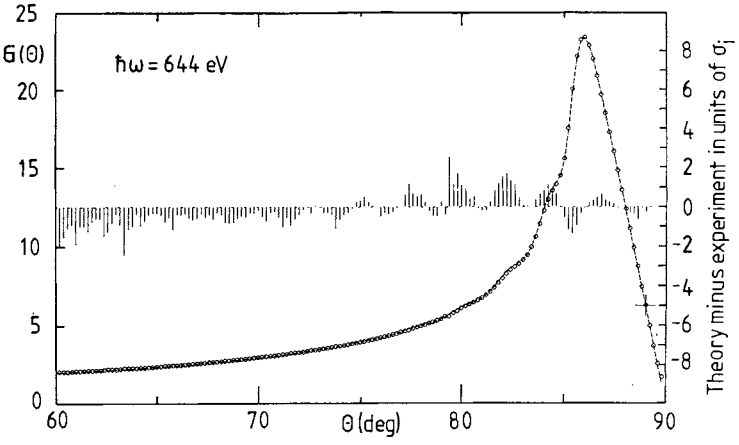

Fig. 8. Relative total yield $G(\theta)$ of a Cu film of 225 Å thickness on white crown glass at $\hbar\omega = 644$ eV. In addition to the experimental $G(\theta)$ spectrum (open circles), the fitted theoretical curve (dashed line) and the deviation between the theoretical and the measured spectra in units of $\sigma_i = 0.01 \times G_{\text{exp}}(\theta_i)$ (vertical bars) are plotted.

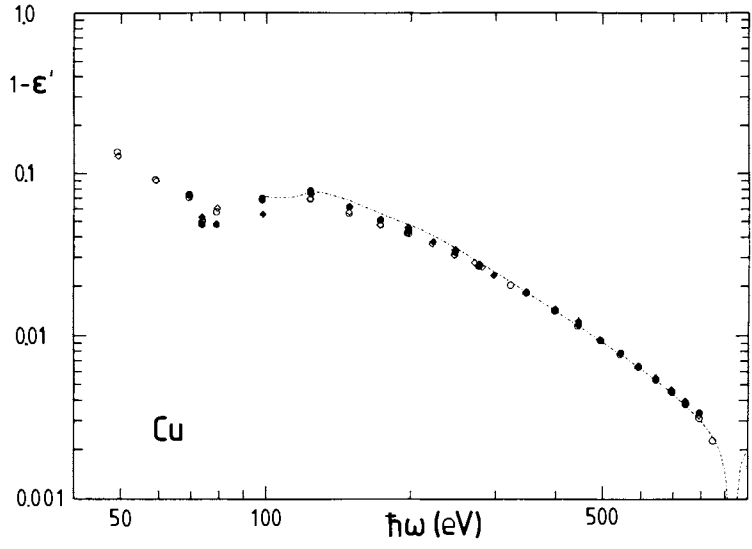

Fig. 9. Real part of the dielectric function ε_{Cu} plotted as $1-\varepsilon'$ versus photon energy $\hbar\omega$. Full symbols result from reflectance measurements, open symbols from total-yield measurements on two samples of 225±5 Å (circles) and 317±6 Å (diamonds). and a slow energy loss due to electron–phonon scattering remains. As a consequence, electrons originating from the substrate, which needs to be a conductor, can contribute to the total yield. A fairly realistic theoretical treatment of such a system appears to be possible. One or two additional parameters for the electron transport would enter the equations. They would have to be fitted together with the other parameters. Their correlation with the other parameters (optical constants) might not be very large, since the characteristic shape of the $G(\theta)$ curves close to the peak would be determined, to a large extent, by the optical constants of the insulator under investigation. Therefore, such a program could yield satisfactory results for this class of materials also. In this case, the method would be expanded beyond its present limitations.

I INTRODUCTION

Optical properties of solids are important in the design of optical elements such as mirrors, prisms, multilayers, and so on. Optical quantities such as the complex refractive index, the reflectivity, or the absorption coefficient are also important for the investigation of the electronic structure of solids. These quantities are most commonly determined by optical

ISBN 0-12-544422-2

methods such as reflection or absorption of light by suitable samples. The electric-field vector of a light wave is perpendicular to its **k** vector. So the electronic system is displaced transversely as a whole, and as a consequence, the electron density is not changed. Today, optical measurements are widely used and with the help of modern synchrotron-radiation sources, a very large energy range can be covered, from the far infrared up to the hard X-ray region.

A completely different method for determining optical constants is the measurement of energy losses suffered by fast electrons, with a kinetic energy of typically 50–300 keV when they are transmitted through thin solid films. In this case the electronic density is modulated longitudinally. The situation resembles the propagation of sound waves through air. The probability for energy losses is determined by the imaginary part of $-1/\varepsilon_L$, which is called the *loss function*. $\varepsilon_L(q,\omega)$ is the longitudinal q- and ω-dependent dielectric function, which in general is different from the transverse function, which is measured by experiments involving transverse light waves. However, for $q \to 0$, ε_T and ε_L become identical, and thus, EELS and optical experiments give the same results. Since this contribution deals with EELS results only, we implicitly assume that only the longitudinal dielectric function ε_L is involved in the formulas and drop the corresponding suffix.

Maxima in the loss function are determined by $\varepsilon_1 \simeq 0$ and ε_2 being "small." Such an excitation is called a plasmon [1].

More than 20 years ago, Raether's group in Hamburg [2, 3] demonstrated that dielectric properties determined by EELS can agree well with those obtained by optical methods. A compilation of older work is given in Refs. [1–4]; more recent work is reviewed in Ref. [5]. These investigations demonstrated the advantages of EELS:

1. Quite a large energy range is available starting at about 0.2 eV. The upper limit is about 2000 eV. It is, however, important to note that the accuracy of optical constants determined by EELS is reduced more and more, starting at about 30 eV, due to multiple-scattering events, which can be corrected only within a limited accuracy. This energy range is available with the help of a laboratory-scale instrument; optical methods at these energies require the use of a large synchrotron-radiation facility.
2. Only bulk properties are measured using EELS. The results are independent of surface preparation or contamination. EELS might be an alternative to optical techniques, when the preparation of an optically good surface is difficult or even impossible.
3. Since EELS is a scattering experiment, it can be performed with a momentum transfer $\hbar q$. This allows the determination of $\mathrm{Im}(-1/\varepsilon\,(q,\omega))$, which contains information about the dispersion of the electronic band structure and electron–electron correlation effects. For the determination

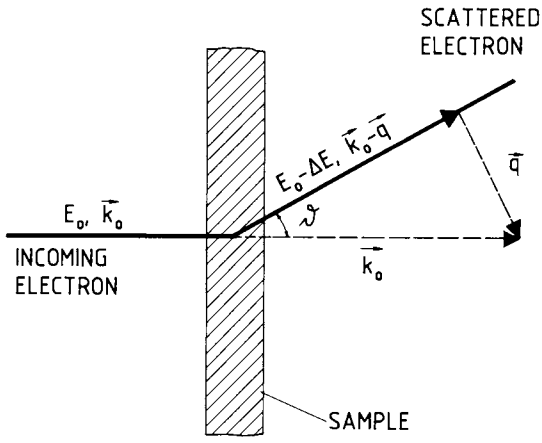

Fig. 1. Scattering geometry of an EELS experiment. An electron with a kinetic energy of typically 50–300 keV penetrating a sample of thickness 500–1000 Å is scattered by an angle ϑ and suffers an energy loss ΔE. The scattering angles are very small, typically several mrad.

of optical constants, however, only the limit $q \rightarrow 0$ is important.

A severe problem is sample preparation, since thin self-supporting samples with a thickness of 500–2000 Å and an area of roughly 1 mm^2 are needed. Many techniques have been applied. A comprehensive overview of many preparation techniques is given in Ref. [5]. However, as experience shows, there is a preparation method for almost every problem. In this chapter we will restrict ourselves to the optical limit ($q \rightarrow 0$), so that the data obtained are comparable to those obtained using optical methods. The determination of optical constants from EELS data will be described in detail. The optical properties of the refractory compounds TiC, VC, TiN, and VN are discussed in detail, and for TiC, a comparison of EELS data with optical data is performed.

DESCRIPTION OF AN EELS EXPERIMENT

The scattering geometry is shown in Fig. 1. A highly collimated beam of monochromatized electrons with a kinetic energy E_o of 50–300 keV and an angular spread $\Delta\vartheta \simeq 0.3$–$0.5$ mrad penetrates a thin sample, typically 500–2000 Å thick. On its passage through the sample, the electron may be scattered inelastically by an angle ϑ and loses an amount of energy ΔE.

Energy and momentum conservation require

$$\Delta E = (\hbar^2/2m)(k_o^2 - k_n^2) \tag{1}$$

$$\hbar q = \hbar(k_o - k_n). \tag{2}$$

Here, k_o and k_n are the wave vector of the unscattered and the scattered electrons, $\hbar$ is Planck's constant divided by 2π, and m is the electron mass. The transferred momentum $\hbar q$ can be decomposed into a parallel and a perpendicular component, to k_o, $q_\parallel$ and $q_\perp$, respectively:

$$\hbar q_\parallel = \hbar k_o \vartheta_E \tag{3}$$

with

$$\vartheta_E = \Delta E/2E_o. \tag{4}$$

This longitudinal momentum transfer is related to the energy loss only.

Similarly, the transverse momentum transfer is given by

$$\hbar q_\perp = \hbar k_o \vartheta, \tag{5}$$

which is independent of the energy loss and depends on the scattering angle only, so that the total momentum transfer is given by

$$\hbar q = \hbar k_o (\vartheta^2 + \vartheta_E^2)^{1/2}. \tag{6}$$

For scattering angles somewhat larger than ϑ_E, the momentum transfer is practically determined by ϑ only. As an example, some numerical values for an electron-energy-loss experiment, used to study the optical properties of a number of refractory compounds, are given [6, 7]. The kinetic energy of the electrons was 170 keV corresponding to $k_o = 228.4$ Å^{-1}. At a characteristic energy loss of $\Delta E = 20$ eV, $\vartheta_E = 0.059$ mrad, which corresponds to $q_\parallel = 0.012$ Å^{-1}. This is, by the way, roughly the same momentum carried by a 20 eV photon (0.01 Å^{-1}).

SCATTERING CROSS-SECTION III

The double-differential scattering cross-section per atom for high-energy electrons in an (infinite) solid is treated in the Born approximation and can be written as [4, 5]

$$\frac{d^2\sigma}{d\omega\, d\Omega} = \frac{4\hbar\gamma^2}{a_o^2 q^4} S(q,\omega) = \frac{\hbar\gamma^2}{(\pi e a_o)^2 N}\frac{1}{q^2}\,\mathrm{Im}(-1/\varepsilon(q,\omega)). \tag{7}$$

Here, in addition, the electron charge e, Bohr's radius a_o and the number density of electrons N per unit volume has been introduced. The factor $\gamma = 1 + E_o/m_o c^2$ makes the result relativistically invariant, where $m_o c^2 =$ 511 keV is the rest mass energy of the electron.

$S(q,\omega)$ is the dynamic structure factor originally derived by van Hove [8]. The second identity of Eq. 7, correlating the dynamic structure factor with the loss function, is derived in Ref. [9]. A derivation of the right-hand side from dielectric theory is given in Ref. [10]. Since the loss function is typically of order unity, the scattering cross-section given by Eq. 7 falls off like $1/q^2$. Using Eq. 6 gives

$$\frac{d^2\sigma}{d\omega\, d\Omega} = \frac{\hbar\gamma^2}{(\pi e a_o)^2 k_o^2}\frac{1}{\vartheta^2 + \vartheta_E^2}\,\mathrm{Im}(-1/\varepsilon(q,\omega)). \tag{8}$$

Thus, measuring the cross-section for inelastic electron scattering gives information on the loss function $\mathrm{Im}(-1/\varepsilon(q,\omega))$.

There are, however, two other contributions that might influence the accuracy of the determination of the volume loss function.

1. In a sample of finite thickness D, excitation of surface modes, also called *surface plasmons*, may take place, which contributes to the scattered intensity. The cross-section for surface-plasmon generation is proportional to

$$\frac{d^2\sigma}{d\omega\, d\Omega} \cong (1/q^3)\,\mathrm{Im}(-1/(\varepsilon+1)). \tag{9}$$

The function $\mathrm{Im}(-1(\varepsilon+1))$ is also called the *surface loss function*.

Surface losses are easily verified, since their cross-section varies like $1/q^3$. On the other hand, their contribution to the observed intensity decreases

as the sample thickness is increased. It was already shown by Raether [2] that even for momentum transfer $q \simeq 0.2\,\text{Å}^{-1}$, the ratio of volume-to-surface losses can be made negligibly small.

2. Radiation losses due to the emission of Cerenkov radiation can take place when the electron velocity exceeds the phase velocity of light. This might occur in highly polarizable materials. It was shown by Kröger [11] that radiation losses, like surface losses, contribute only at very small angles.

The usual way to suppress contributions from surface and radiation losses is to perform the measurements at a finite momentum transfer q, which is small enough so that the optical limit $q \to 0$ is still valid, but which is large enough so that only volume losses contribute. In the case of refractory compounds reported later in this article, $q = 0.1$–$0.15\,\text{Å}^{-1}$ was found sufficiently small.

IV EXACT DETERMINATION OF THE LOSS FUNCTION

To determine the exact loss function from a spectrum measured at small q, as described in the preceeding section, corrections for finite spectrometer resolution and multiple scattering have to be applied. Both energy and angular resolution of a spectrometer are finite, and therefore the observed intensity at some energy and angle is a convolution of Eq. 8 with the energy- and angular-resolution function. The problem is simplified on assuming that $\text{Im}(-1/\varepsilon(q,\omega))$ is constant over the resolution interval. This assumption is fulfilled, since energy resolution typically is of the order of 0.1 eV, and the momentum transfer resolution is typically $<0.05\,\text{Å}^{-1}$. Then the convolution problem leads to a correction factor $F(\Delta E)$, which depends on the energy loss only. The whole procedure has already been described in detail in Ref. [3]. To make all corrections properly, the energy and angular resolution are recorded before each measurement, in order to calculate $F(\Delta E)$ exactly. For the spectrometer resolution given previously, the correction by $F(\Delta E)$ is below 10% and does not vary much with the energy loss.

The scattering cross-section for highly energetic electrons in solids is very high, and mean free paths are of the order of a few hundred angstroms. Therefore, there exists a probability that an electron undergoes more than one scattering event on traversing the sample. In the range of roughly twice the plasma energy, up to energy losses of 40–50 eV, only double scattering events contribute significantly and therefore have to be corrected for.

Double scattering can be described as a convolution of a "true" single-scattering spectrum with itself. In this way dominant structures like volume plasmons are also found at twice the single-energy loss. Triple losses lead to losses at three times the single-loss energy, and so on.

Several numerical deconvolution schemes have been developed [12] and applied to EELS data [3, 4, 13, 14]. Following Ref. [3], double scattering can be calculated starting at low-energy losses up to about 1–2 eV, where double scattering is negligibly small. Then, the double-scattering contribution can be calculated at slightly higher energies and subtracted from the uncorrected spectrum. By this step-by-step method, the whole spectrum can be corrected. At the end of the procedure, the loss function is determined experimentally except for a multiplicative constant. It is possible to measure the absolute value of the loss function experimentally [2, 3] but this method is not very accurate. Instead, it is preferable to use a suitable sum rule derived from the Kramers–Kronig relations for normalization.

KRAMERS–KRONIG ANALYSIS V

The causality principle connects imaginary and real parts of a complex function via the Kramers–Kronig (K–K) integrals. Many optical spectroscopies make use of these relations. In the case of EELS at small momentum transfer ($q \rightarrow 0$), the K–K transform is given by

$$\mathrm{Re}(-1/\varepsilon(\omega)) - 1 = \frac{2}{\pi} P \int_0^\infty \mathrm{Im}(-1/\varepsilon(\omega')) \frac{\omega' \, d\omega'}{\omega'^2 - \omega^2}. \tag{10}$$

where P denotes the Cauchy principal value of the integral. Two extrapolations are necessary in order to perform the integral form zero to infinity. From zero to about 0.5 eV the loss function is interpolated linearly starting at zero, since in the original data this region is obscured by the primary beam. At higher energies, above 40–50 eV, the loss function is extrapolated proportional to ω^{-3}, which is the loss function of a free-electron gas. The proper normalization of the loss function can be obtained from Eq. 10 by setting $\omega = 0$:

$$\mathrm{Re}(-1/\varepsilon(\omega = 0)) - 1 = \frac{2}{\pi} P \int_0^\infty \mathrm{Im}(-1/\varepsilon(\omega')) \frac{d\omega'}{\omega'}. \tag{11}$$

For metals, $1/\varepsilon(\omega=0)=0$. For insulators and semiconductors ε is real below the band gap and can be obtained from the refractive index by $\varepsilon_1=n^2$. The advantage of using Eq. 11 for normalization is this: the measured spectrum is weighted inversely proportional to the energy loss. Thus, the energy region is weighted most where multiple losses contribute only little and the loss function is therefore determined with the highest accuracy. The well-known *f*-sum rule,

$$\int_0^\infty \mathrm{Im}(-1/\varepsilon)\omega \, d\omega = \pi/2\omega_p^2. \tag{12}$$

which in principle can also be used for normalization of $\mathrm{Im}(-1/\varepsilon)$, weights the loss function proportional to ω. In addition, an assumption for the electron density N, which enters into the plasma frequency

$$\omega_p = (4\pi Ne^2/m)^{1/2} \tag{13}$$

has to be made. This can be avoided by using Eq. 11.

VI BRIEF SUMMARY OF THE EVALUATION PROCEDURE

To give an overview over the evaluation procedure, the five steps leading to readily evaluated data from EELS measurements will be briefly summarized.

(1) Measurement of the angular- and energy-resolution functions.
(2) Measurement of the loss spectrum.
(3) Angular and energy deconvolution.
(4) After correction for double scattering, the unnormalized loss function $\mathrm{Im}(-1/\varepsilon)$ is obtained.
(5) Kramers–Kronig analysis and normalization of the loss function using Eq. 11. Calculation of ε_1, ε_2, n, k, and so on.

VII COMPARISON WITH REFLECTIVITY MEASUREMENTS

During the last years, EELS has been used by the Karlsruhe group in a number of experiments to elucidate the dielectric properties in the energy

range 0.5–40 eV. Examples include the study of the binding states in amorphous hydrogenated carbon coatings [15], conducting polymers [16–22], carbides and nitrites of 3d and 4d transition metals [6, 7], A-15 superconductors [23], and, most recently, ceramic superconductors [24–26].

As an illustrative and representative example, the dot-dashed curve in Fig. 2 shows the measured loss function of TiN after the elastic line has been subtracted, and the energy and angular deconvolution was performed. The energy range extends from 0–40 eV. The solid line shows the influence of the double-scattering correction as described in Ref. [3]. It is seen that at higher energies this correction is quite substantial, whereas below about 20 eV it is less important. The maximum of the curves is arbitrarily normalized to 25. The solid curve is the input spectrum for the K–K analysis. The normalization of the loss function is then performed using Eq. 11.

In Fig. 3, optical data are shown for TiC obtained with different methods. A comparison is made between the optical constants derived by the procedure described above taken from Pflüger *et al.* [6] with data from Lynch *et al.* [27] deduced from reflectivity measurements using synchrotron radiation in the energy range 0.1–30 eV. To our knowledge, these are the only available optical measurements on refractory compounds over a large energy range comparable to that covered by EELS. The upper part of Fig. 3 shows the measured reflectance from Ref. [27] versus reflectance derived

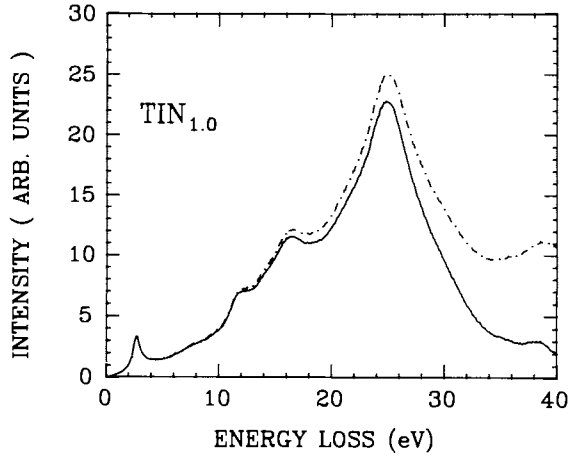

Fig. 2. Energy-loss intensity of TiN after the elastic line has been subtracted and angular deconvolution has been applied. The dot-dashed curve is without correction for double scattering. The solid curve is corrected for double scattering. Above about 20 eV, the correction becomes substantial.

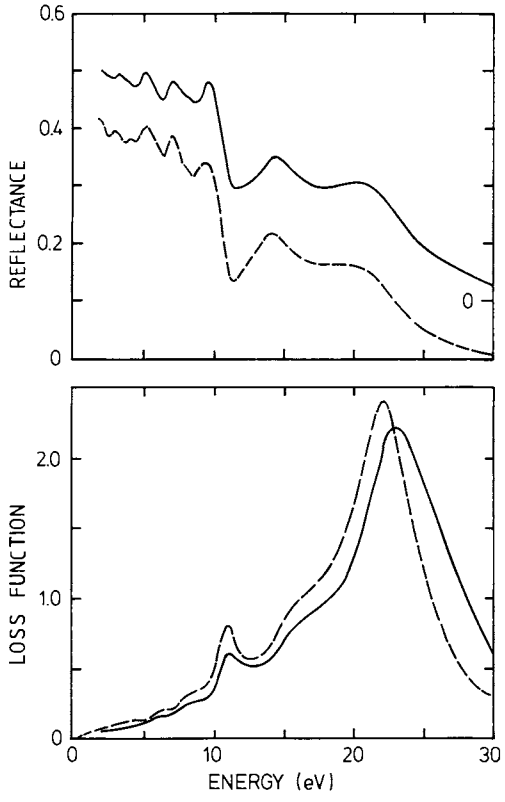

Fig. 3. Comparison of optical constants obtained with EELS taken from Ref. [6] with those obtained with reflectance measurements from Ref. [27]. Solid lines indicate data derived from EELS measurements. Dashed lines indicate data derived from reflectance measurements. Note the 0.1 upward shift of the solid-line curve in the upper figure.

from EELS data. Note that the scale of the EELS curve is shifted upward by one tick mark. The lower part of Fig. 3 shows the opposite comparison. The loss function calculated from reflectivity data, reproduced in Ref. [27], is compared to the loss function measured by EELS.

The data obtained by the two methods agree remarkably well. Generally the reflectance obtained by EELS differs less than reflectance data for TiC published earlier [28, 29].

Each method shows its particular strength and weakness. At about 25 eV, the EELS reflectivity seems to be too high compared with the optical data, whereas the EELS volume plasmon, at 23.5 eV, is slightly higher than that derived from optical data. Also, some structures in the EELS spectra are broader and less pronounced than in the optical curves. One possible explanation for this is the completely different method of

sample preparation. Large, carefully polished zone-melted single crystals were used by Lynch *et al.* Thin, self-supported 770 Å-thick polycrystalline films of TiC were prepared by reactive sputtering for the EELS measurements. In both groups great care was taken for a good characterization of the samples.

VIII OPTICAL PROPERTIES OF TiC, VC, TiN, AND VN

In this section we briefly review the dielectric properties of the refractory compounds TiC, VC, TiN, and VN as determined by EELS [6]. Similar experiments were also performed on ZrN, NbC, and NbN [7]. For a complete description the reader is referred to these references.

The properly normalized loss functions together with the real and imaginary parts of the dielectric function are shown in Fig. 4 for TiC, VC, TiN, and VN. One realizes that maxima in the loss functions correspond to $\varepsilon_1 \simeq 0$ and small ε_2. The better this condition is fulfilled, the more pronounced is the structure of the loss function. The real and the imaginary part of the refractive index of these compounds is given in Tables I–IV.

The dominant feature in all loss spectra is the volume plasmon, the collective oscillation of all valence electrons, found at 23.5, 24.9, 24.9, and 26.3 eV for TiC, VC, TiN, and VN, respectively. These values might be compared to the plasma energy defined by Eq. 13 taking into account the metal 4s and 3d and the nonmetal 2s and 2p orbitals. One obtains 23.3, 25.5, 25.5, and 28.0 eV, which is in quite satisfactory agreement.

Apart from the main plasmon peak, there are other excitations that are caused by interband transitions, and therefore might be termed interband plasmons. Spectra of the carbides and nitrides look quite different, but there is some similarity between TiC and VC and between TiN and VN. These differences between carbides and nitrides are, however, closely related to the electronic structure of these compounds.

In the vicinity of the Fermi level, the electronic states of the refractory compounds consist of bonding nonmetal p orbitals strongly hybridized with metal d orbitals below, and antibonding d orbital hybridized with nonmetal orbitals above E_F [30]. Hybridization is stronger for the carbides than for the nitrides. The Fermi level is determined by the number of available valence electrons. For TiC it lies in the very minimum between p and d states, whereas for VC, TiN, and VN it is shifted more and more upward into the d bands.

Many features of the loss spectra can be understood from details of the electronic structure. For a comparison with calculated band-structure data,

the optical joint density of states (OJDS), which is defined as [31]

$$I_1(\omega) = 2\omega\varepsilon_2(\omega)/\pi\omega_p^2 \tag{14}$$

was calculated from ε_2 as derived from the K–K analysis.

Fig. 5 shows a comparison between the OJDS (solid curve) and joint densities of states (dashed curve) derived from self-consistent Gaussian LCAO band-structure data [32]. The joint density of states gives a measure for the probability of interband transitions when matrix elements as well as lifetime effects are neglected. Many structures seen in the OJDS are also reflected by the calculations. The maximum (around 7 eV), which is present in all compounds, can be attributed to transitions between the

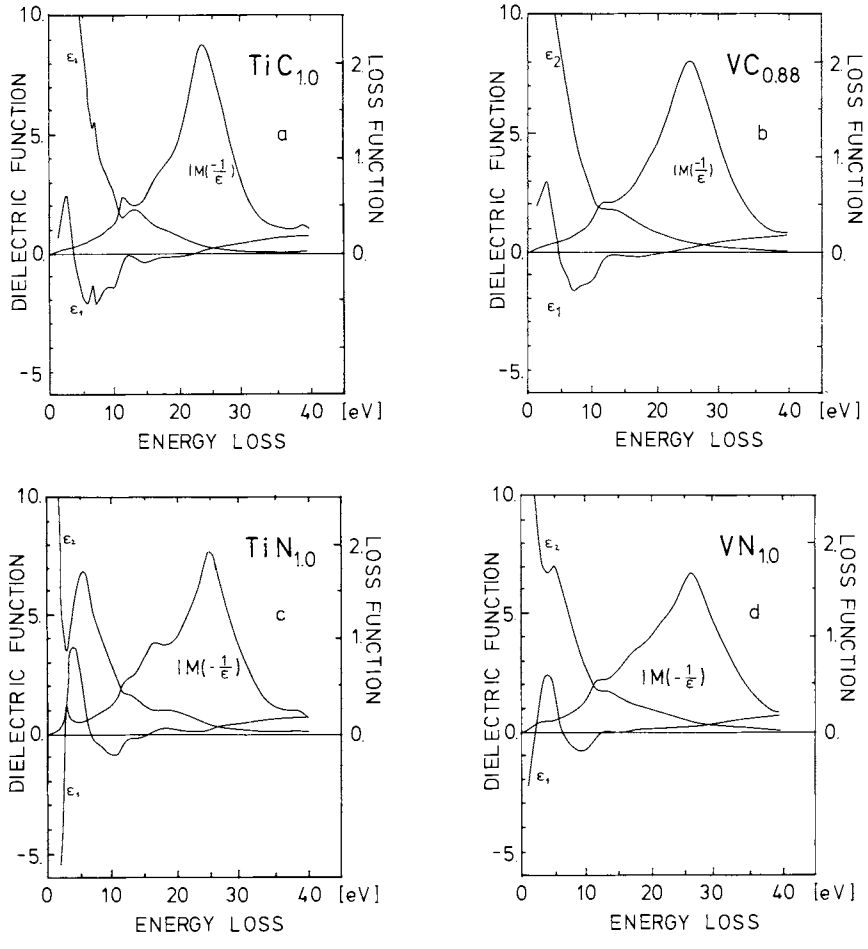

Fig. 4. Loss functions and Kramers–Kronig-derived real and imaginary parts of the dielectric function ε_1, ε_2 for (a) $TiC_{1.0}$, (b) $VC_{0.88}$, (c) $TiN_{1.0}$, (d) $VN_{1.0}$.

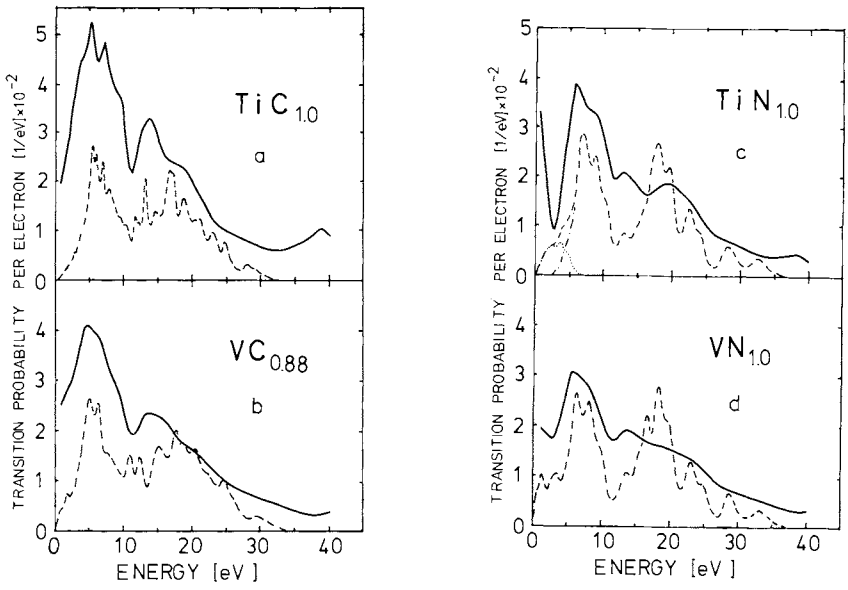

Fig. 5. Kramers–Kronig-derived optical joint densities of states of the stochiometric compounds (solid lines) and joint densities of states from our band-structure calculation (dashed lines) for (a) $TiC_{1.0}$, (b) $VC_{0.88}$, (c) $TiN_{1.0}$, (d) $VN_{1.0}$. In the TiN curves, the joint density of states for transitions between d bands and without d-d transitions are shown separately (dotted and dotted-dashed lines, respectively).

occupied p to unoccupied d states. Especially in the nitrites, the Fermi level lies well within the d bands. Transitions between these d states are dipole-forbidden. Thus, up to about 2.5–3 eV, interband damping is very weak. This is most clearly seen in the TiN curve. To emphasize this, the contribution of d-d transitions to the joint density of states for TiN in Fig. 5 is also shown (dotted curve in Fig. 5c). The onset of strong p-d transitions is observed above 2.8 eV. Below 2.8 eV the OJDS in Fig. 5 is dominated by intraband transitions. The strong minimum at 2.8 eV is, of course, also seen in ε_2. This weak interband damping (small ε_2) at this energy therefore ensures that the Drude plasmon (the collective oscillation of the free electrons, which is shifted down by strong interband transitions at higher energies) can be observed at 2.8 eV in TiN, and from the OJDS curve, Drude parameters that agree well with other published data can also be obtained [6, 33–35]. This low-energy plasma excitation is also observed in VN, but there much more damping occurs.

Since in the carbides E_F lies in the middle between p and d states, interband transitions down to very low energies are possible. Therefore, ε_2 is high in that energy range so that collective oscillations are strongly damped. The same observation was also made by Lynch *et al.* on TiC [27].

This example shows how optical properties determined by EELS can be

used for a detailed comparison with theoretical band-structure data and thus can help to understand the electronic structure of these compounds.

Chapter 14

Optical Parameters for the Materials in *HOC I* and *HOC II*

EDWARD D. PALIK
Institute for Physical Science and Technology
University of Maryland
College Park, Maryland

I. Introduction 313
II. The Parameters 313
References 334

INTRODUCTION I

We have collected several optical parameters that are useful in characterizing the materials in *HOC I* and *HOC II*. Some of these parameters were obtained directly from the critiques; others were found in references given in the critiques; still others were found in other references, in review articles, and in other general references such as handbooks. Some of these articles, review articles, and handbook articles are listed in the references [1–11]. Especially useful has been Ref. [4]. It was not feasible to list the many specific original references for each material, although a few have been included as Refs. [13–35].

THE PARAMETERS II

The column headings in Table I are as follows:

(1) *Chemical formula of material.*

(2) *Most common crystallographic form of the material at room temperature.* The materials fall into many of the 32 point groups (crystal classes) and the 14 Bravais lattice classifications shown in Fig. 1.

(3) and (4) *The space group in the X-ray and spectroscopic notation.*

Copyright © 1991 by Academic Press.
All rights of reproduction in any form reserved.
ISBN 0-12-544422-2

(5) *The dimensions of the unit cell.* This will include an angle when it is not 90°. Figure 1 will suggest if the angle is not 90°.

(6) The number of molecular units in the unit cell.

(7) *The number of molecular units in the primitive (Bravais) cell.* This number is important in determining the total number of optic modes, $3N$-3, where N is the number of atoms in the primitive cell. We will generally use the term *optic* mode to rhyme with *acoustic* mode.

(8) *The irreducible representation.* Each term designates one of the

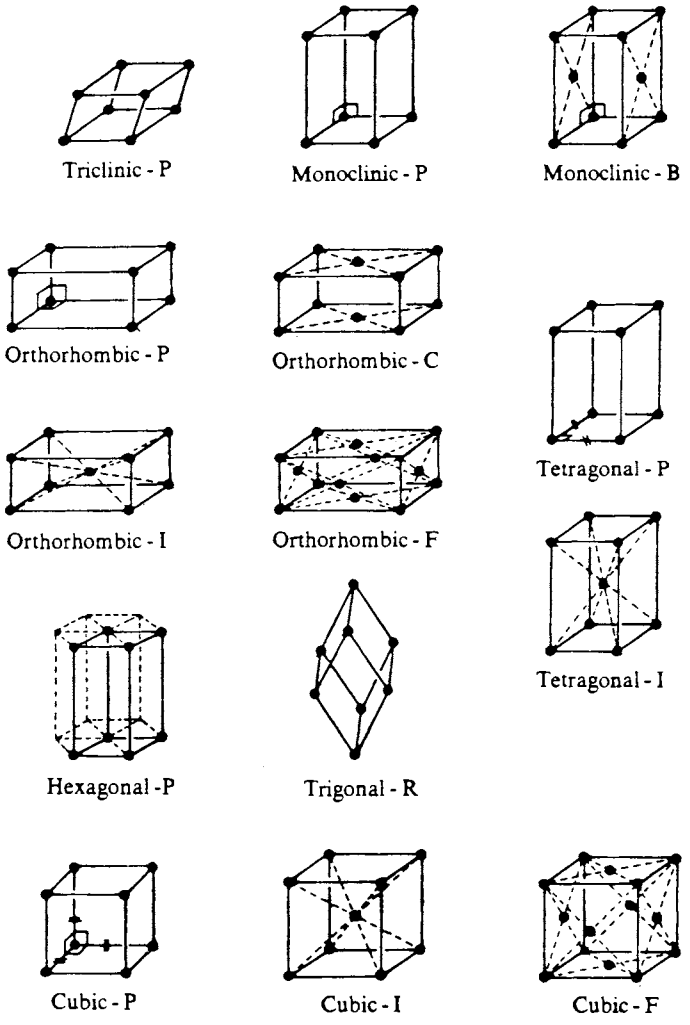

Fig. 1. The unit cell for each of the 14 Bravais lattices (from Burns and Glazer [5], copyright 1978, Academic Press).

types of optic modes allowed; IR, R, and O represent infrared, Raman, and silent activity. A and B have single degeneracy, E has double degeneracy, and F has triple degeneracy. In most cases subscripts u and g specify IR and R activity, respectively. The three acoustic modes have already been subtracted off.

(9) *Total number of optic modes in the crystal as obtained from* $3N$-3 *or from examination of the irreducible representation.*

(10) *Transverse optic* (TO) *phonon frequencies with their species and ordinary (o)/extraordinary (e) designations.* Generally, group-theory analysis is done on the basis of the symmetry transformation properties of the e_x, e_y, and e_z displacements of the atoms from their equilibrium positions. The members of the irreducible representation that are IR-active are associated with the transverse optic phonons with displacements in the x, y, z directions, but the directions of propagation are not necessarily specified.

(11) *Longitudinal optic* (LO) *phonon frequencies with their species and ordinary (o)/extraordinary (e) designations.* The radiation electric field is $\|$ to the optic axis (e) or $\perp$ to the optic axis (o). In the irreducible representation for a cubic material, we can associate any particular IR term (F, for example) with two TO modes and one LO mode, thinking of them as propagating in the same direction as the direction of the EM wave with which we measure them. This suggests that the LO mode should be IR active. But it does not produce absorption, except in a special case of a thin sample measured at nonnormal incidence with p-polarization [12]. In this case the component of E$\perp$ to the film can drive (couple to) the long-wavelength LO phonons (propagating $\perp$ to the film surface), and an absorption line appears. This is related to the fact that the dipole matrix element for LO phonons in bulk materials is zero, although the mode (or rather its displacement direction) is IR-active. The activity becomes apparent in the nonnormal-incidence case. For nonpolar crystals such as Si, all three modes are degenerate, IR-inactive and R-active. For polar cubic crystals such as GaAs, the LO mode is raised slightly in frequency above the two still-degenerate TO modes; the two TO and one LO modes are IR-active and R-active, also. (Notice that the LO mode is not seen directly in IR as an absorption line for the reasons discussed above.)

For some simple cubic crystals, large anharmonic effects produce multiple structure in the reststrahlen spectrum above TO, which precludes a Lorentz-oscillator fit and obscures the LO frequency. We can still choose the $n = k$ wavelength farthest above TO (but not to the band gap yet) as the definition of LO and list this number in parentheses in Table I. Otherwise, the LO frequency is directly obtained from a simple Lorentz-oscillator fit (where $n = k$) or from Raman measurement (if selection rules permit). In studying the literature, we have found that values of TO and LO from R and IR data often vary by 5 cm^{-1} from lab to lab. This is disquieting, suggesting poor spectroscopic calibration for R and IR experiments and/or

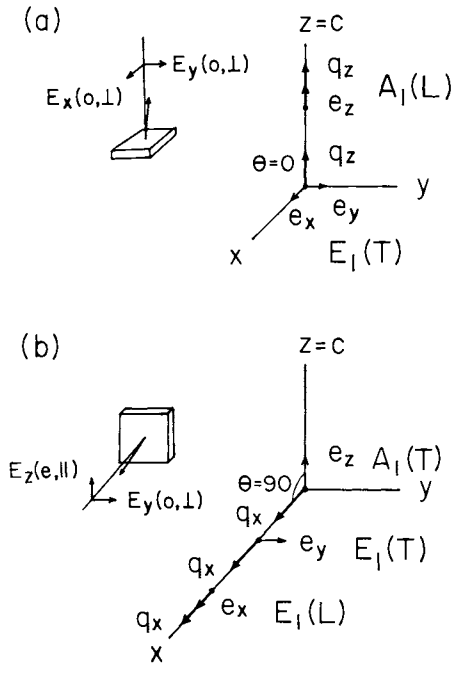

Fig. 2. (a) Wave vector q_z for a transverse optic mode $E_1(T)$ with its accompanying lattice displacement e_x and e_y; and wave vector q_z for a longitudinal optic mode $A_1(L)$ and its accompanying lattice displacement e_z. The inset shows the sample with $E_x(o, \perp)$ and $E_y(o, \perp)$ electric fields. Direction of phonon propagation is parallel to the $z=c$ optic axis for $\theta=0$. (b) Wave vector q_x for a transverse optic mode $A_1(T)$ with its accompanying lattice displacement e_z; wave vector q_x for a transverse optic mode $E_1(T)$ with its lattice displacement e_y; wave vector q_x for a longitudinal optic mode $E_1(L)$ with its lattice displacement e_x. The inset shows the sample with E_x $(e, \|)$ and $Ey(o, \perp)$ electric fields. Direction of phonon propagation is perpendicular to the $z=c$ axis for $\theta=90°$.

poor material or poor model analysis for IR. It is not obvious that recent data are calibrated any better than older data.

For a uniaxial crystal (all noncubic crystals in Table I are uniaxial except for As_2S_3, As_2Se_3, ThF_4 and CuO), the situation is more complicated. For wurtzite structure for phonon wave vector $q(z)$ parallel to the $z=c$ optic axis ($\theta=0$), the degenerate TO modes ($E_1(T)$, lattice displacement $e\|x, \|y$) and the LO mode ($A_1(L)$, lattice displacement $e\|z$) appear in the Raman experiment when the appropriate polarizations for incident and scattered light are used. They also appear in the IR experiment with the proper polarization (Fig. 2a). They are designated as $E_1(T)$, $E_1(T)$ and $A_1(L)$. For phonon wave vector $q(x)$ perpendicular to the $z=c$ axis ($\theta=90°$), the nondegenerate TO mode ($E_1(T)$, $e\|y$) and the LO mode ($E_1(L)$, $e\|x$) can

appear in R, as well as the TO mode ($A_1(T)$, $e\|z$). They also appear in the IR experiment with the proper polarization (Fig. 2b). They are designated as $E_1(L)$, $E_1(T)$, $A_1(T)$. A number of uniaxial materials have been studied for wave vectors varying from $\theta = 0$ to $\theta = 90°$. Such a measurement reveals how the modes shift in frequency and symmetry as the direction of phonon propagation changes. In the Tables a–p accompanying Table I, we have tried to indicate this behavior by listing the TO and LO frequencies of each symmetry for $\theta = 0$ and $\theta = 90°$. An arrow then indicates how a given mode shifts in frequency and symmetry as the direction of propagation changes. This is relatively simple for wurtzite crystals but complicated for x-SiO_2, for example. Luckily, most wurtzite crystals have small force-constant anisotropies for directions of vibration $\|$ and $\perp$ to the c axis, and the symmetry-species designations in Table d hold. For large force-constant anisotropies, the assignment of symmetry species can be quite different. This hinges on whether as the **q** vector is "tipped" from $\theta = 0$ to $\theta = 90°$, the lattice displacement can also "tip," or remains along the same direction.

Modes only R-active or O-silent are listed at the bottom of the TO column (they do not affect the optical constants). These are often TO modes not accompanied by an LO mode (as are the polar modes discussed above), but LO modes are often Raman-active, also.

If the modes are both R- and IR-active, the pertinent reststrahlen reflection spectrum can be "constructed" approximately from the TO and LO frequencies (and their line widths) determined from Raman scattering. For wurtzite crystals, the $\theta = 0$, $E_1(T)$ mode has an accompanying $\theta = 90°$, $E_1(L)$ mode forming the reststrahlen peak for the $E \perp c$ ordinary-ray polarization with sample plane $\perp c$. This LO mode is to the right and one line down from the TO mode in the Table d listing. Of course, an $E \perp c$ spectrum can also be obtained from a sample cut with the c axis in the plane of the sample. Such a sample then allows the $E\|c$ spectrum to be measured, also. Now the $\theta = 90°$, $A_1(T)\|$ mode has an accompanying $\theta = 0$, $A_1(L)\|$ mode (one column to the right and one row down) forming the reststrahlen peak for the $E\|c$ extraordinary-ray polarization. Thus, a Lorentz-model analysis of the reflection spectrum gives $A_1(T)\|$ with $e\|z$ (direction of vibration of the transverse mode) and $A_1(L)\|$ with $e\|z$ (now the direction of vibration of the longitudinal mode). Of course, no absorption line is seen at ω_L where $\varepsilon_1 = n^2 - k^2 = 0$. By and large, independent measurements of R and IR spectra in various labs give results in agreement within $10\,cm^{-1}$. This again indicates the wide variations in measured frequencies from lab to lab.

In more complicated systems such as x-SiO_2 (Table m) for the pairs of T and L modes, the L mode is adjacent to the T mode on the same line or the L mode is one line down, depending on the pairing scheme.

Some types of uniaxial crystals have not been studied in detail by Raman scattering for wave vectors varying from $\theta = 0$ to $\theta = 90°$, perhaps because

These calculated frequencies are usually within 5 cm^{-1} of the observed frequencies. The translation modes (acoustic phonons) $B_{3u} + B_{2u} + B_{1u}$ are included in this example but not in the irreducible representation. While the acoustic-phonon modes are not IR-active, they are included in the IR column because of the *u* subscript. They should be active in Brillouin scattering, however. Most of the other observed modes in the IR are combination bands of these fundamentals [32–34].

the IR-active modes are not also R-active. In this case we state only the T and L modes omitting the arrows.

It is interesting to note the differences in R and IR experiments. Raman measurements are very specific as to which phonon mode is being measured because of the constraints on wave vector and energy. Infrared measurements do not have the constraint of wave-vector conservation. Therefore, for the configuration of Fig. 2b, many TO phonons traveling in many directions in the x, y plane (and for that matter, other directions having a component of dipole moment $\|E$) contribute to the absorption line seen for $E\|c$ (they may not all have the same frequency). The imaginary part of the IR transverse dielectric function ($\varepsilon_2 = 2nk$) has a peak at ω_T. The real part of the transverse dielectric function ($\varepsilon_1 = n^2 - k^2$) usually has a zero very near here, and it usually has a second zero above ω_T at ω_L. This zero is presumably at the frequency of the LO phonon propagating $\|c$.

If the unit cell has a center of symmetry, modes are mutually exclusive; an R-active mode is not also IR-active and vice versa.

In the optic frequency Tables a–p, a notation such as $E(L)(\text{IR}\perp)$, $A(L)(\text{IR}\|)$ indicates that the E and A modes are IR-active (their transverse members are seen; the longitudinal members are not seen because of dipole-moment, matrix-element considerations, but we can obtain their values from an oscillator fit of the reststrahlen reflectivity by finding where $\varepsilon_1 = 0$).

(12) and (13) *Plasma frequency.* Metals have plasma frequencies typically in the VIS–UV because of their large free-carrier (usually electron) densities (10^{22}–$10^{23}\,\text{cm}^{-1}$). Since semiconductors can be doped with controlled amounts of impurities, their free-carrier plasma frequencies can be varied. We therefore omit this parameter for semiconductors. The Drude plasma frequency ω_P^2 (rad/s) is given by the formula $\omega_P^2 = 4\pi Ne^2/m^*\varepsilon$ with N in cm^{-3}; $e = 4.77 \times 10^{-10}$ esu; m^* is the effective mass compared to the free-electron mass of 9.10×10^{-28} gm; ε is the background lattice dielectric constant at the plasma frequency. The values of ω_P for a given material obtained from different laboratories often vary by tens of percent, so we use the fewest possible number of significant figures, namely two. A polariton composed of a coupled EM wave and the plasmon can exist in the region where ε_1 is negative (from 0 to ω_P) and is measurable by a total internal reflection technique in ω–q space, where q is the polariton wave vector.

Three ways of determining ω_P are fitting the reflectivity with a Drude model; measuring the energy loss of an electron beam passing through a thin layer; and determining where the real part of the dielectric function is zero ($\varepsilon_1 = n^2 - k^2 = 0$). This last criterion is easy to determine for the metals in the Tables in *HOC I* and *HOC II*. When interband absorption effects are small, n crosses k at only one point in the VIS–UV and this point often agrees with a Drude-model fit (which ignores interband effects). However,

for some metals, $n = k$ occurs at two, three, or four wavelengths, and the definition is obscured. This is usually due to strong interband transitions giving strong absorption/dispersion effects.

For metals, semiconductors, and insulators the valence (bound) electrons also produce a plasma effect in the interband region usually at a frequency higher than the free-electron plasma frequency for a metal. For a metal the first zero should locate the free-electron plasma frequency and the third should locate the valence plasma frequency. Between the second and third zeros, ε_1 is negative and a valence plasma polariton should be definable just as a free-electron plasma polariton in ω–q space is definable from 0 to ω_P. Ideally for a semiconductor or insulator, this valence plasma frequency is at the second zero (above the band gap). The polariton mode is confined between the first and second zeros in ε_1 above the band gap in the spectral region where ε_1 is negative. These frequencies are listed in the $n = k$ column, although with overlapping interband effects, the valence plasma frequency may not be pinpointed by the second zero (higher-energy zero) of each pair of zeros. In Table I, in the $n = k$ column for some of the materials, there is no crossing (dashed line); in other cases there are two sets of data that differ, and the crossing cannot be pinpointed (crosses); in still other cases, no data are available in the interband region, and the space is left blank.

In addition to a phonon resonance producing a zero in ε_1 very close to ω_T for a semiconductor and insulator, the zero somewhat above the resonance allows a longitudinal mode to exist: ω_L, for example. This idea is straightforward for lattice vibrations. It also holds for the free-carriers in metals and doped semiconductors, which have a resonant frequency at $\omega = 0$ and an ω_P (a longitudinal propagating plasmon) at $\varepsilon_1 = 0$. However, the interband region (especially at the second of each pair of zeros) and the nature of the longitudinal mode are not so clear.

(14) *The fundamental band gap E_g of semiconductors and insulators.* The analysis of the absorption coefficient to extract E_g is model-dependent for indirect (i) and direct (d) energy gaps. In lieu of a model fit, some investigators just define E_g as the point at which the absorption coefficient $\alpha = 4\pi k/\lambda = 100$–$1000\ \mathrm{cm}^{-1}$.

(15) *The dc dielectric constant ε_0.* The real part of ε_0 near $\omega = 0$ for insulators is a positive number, which is straightforwardly determined from low-frequency optical or capacity experiments. However, for doped semiconductors and metals ε_0 tends to large, negative values because of the free-carrier dispersion. According to the Drude model, $\varepsilon = \varepsilon_1 + i\varepsilon_2$ contains components $\varepsilon_1 = \varepsilon_\infty\,[1 - \omega_P^2/(\omega^2 + w_\tau^2)]$ and $\varepsilon_2 = \varepsilon_\infty\,\omega_P^2\,\omega_\tau/\omega(\omega^2 + \omega_\tau^2)$ with $\omega_\tau(s^{-1}) = 1/\tau$, where $\tau(s)$ is the free-carrier lifetime and ω_τ is the damping constant. However, ε_2 approaches infinity as $\omega \to 0$. To escape this "dilemma," we can switch our attention to the real part of the electrical conductivity. Since $\sigma = -i\varepsilon\omega/4\pi$, then $\sigma_1 = \varepsilon_2\,\omega/4\pi = \varepsilon_\infty\,\omega_P^2\,\omega_\tau/4\pi(\omega^2 + \omega_\tau^2)$. The dc conductivity is given by $\sigma_0(s^{-1}) = \varepsilon_\infty\,\omega_P^2/4\pi\omega_\tau$, a finite num-

ber. The resistivity $\rho_0(s) = 1/\sigma_0$; $\rho_0(\text{ohm cm}) = 9 \times 10^{11}\ \rho_0(s)$. For metals $\varepsilon_\infty = 1$; for semiconductors $\varepsilon_\infty \simeq 4 - 16$.

We do not include the high-frequency dielectric constant ε_∞. The real part of ε_∞ for a metal is generally taken as unity in the X-ray region. For a semiconductor or insulator it is usually defined in connection with the Lorentz-model fit to reststrahlen reflectivity data; it is the value of ε_1 below the fundamental band gap where ε_1 is nearly a constant before the lattice-vibration dispersion begins to decrease ε_1 significantly.

INTRODUCTION I

We present data below for several metals: the alkali metals Li, Na, and K, and the transition metals Cr, Fe, Nb, and Ta. There are some other data compilations that it may be useful to consult. Weaver *et al.* [1] present optical data for noble metals, transition metals, lanthanides, actinides, and a few other metals. They present plots that show the agreement, or lack thereof, of data from many investigators. The spectral region covered is usually up to 200 eV or less. Henke *et al.* [2, 3] present calculated atomic scattering factors, and derive an empirical set of data based on experimental results. The spectra range is 10–10,000 eV. Actual data do not exist over most of this range, and some of the data presented were taken on atoms (vapor samples) and some on solids.

II ALKALI METALS

The alkali metals are the simplest of all metals, and their dielectric functions the simplest and best understood. The nearly-free-electron model should be valid. The Fermi level should lie about in the middle of the lowest conduction band, and the gap between the bands at the zone boundaries should be small. The Fermi surface should be spherical, and all interband optical transitions should occur in a central spherical region of the Brillouin zone. The interband optical properties should be accurately calculable by perturbation theory [1–3]. Indeed this might be the case for all alkali metals except Li. Li has only three electrons per atom, with a $1s^2 2s$ configuration. In a pseudopotential approach, there are no core p electrons to which the 2p part of the valence electrons can be orthogonalized. Consequently, the pseudopotential is not as small as for other alkali metals, and the band gap is larger. The Fermi level then comes closer to the zone boundary, and the Fermi surface is distorted from a sphere. Another view is that the screening of the core potential by the single 2s valence electron of the atom is less effective in Li than by the corresponding electrons in the other alkali metals, and the gap is consequently larger. Thus, Li is expected to be somewhat different from the other alkali metals, and this is borne out by experiment.

In fact, however, recent photoemission measurements [4, 5] show that the apparent filled region of the valence band in Na and K (and presumably other alkali metals) is narrower than band-structure calculations show. This is an effect of the response of the conduction electrons to the photohole, that is, one should not interpret photoelectron spectra (or optical spectra) on the basis of the one-electron density of states, but rather the spectral density of the interacting system of electrons. An equivalent picture is to augment the calculated one-electron band structure by the (complex) self energy, which shifts bands nonuniformly and broadens them [6–9].

The experimental situation is complicated by several factors. The alkali metals are reactive. They have low melting points, and relatively high diffusion rates at room temperature, leading to surfaces that are possibly rough. A number of measurements were taken not at free metal surfaces, but at quartz–alkali metal interfaces to avoid contamination, even in ultra-high vacuum, and to yield a smooth interface. The roles of interfacial grain structure, reactions, and strain are unknown. A number of years ago, a significant peak in the optical conductivity was reported for several alkali metals, with potassium being the most studied [10, 11]. The peak occurred at an energy lower than the threshold for interband absorption. Many theoretical explanations were proposed in the ensuing years, but that peak was not found in many subsequent measurements, especially, but not

exclusively, those made on the quartz–metal interface. The best early explanation was that it arose because of roughness at the alkali metal–vacuum interface [12]. Some experiments showed that it may be present only when water is adsorbed on the alkali metal surface [13]. This led to a new interpretation, that it arose from charge-density waves, at least in potassium [14, 15]. Subsequent measurements did not confirm the predicted optical structures [16]. A final complication is the fact that at low temperatures both Na and Li undergo a structural phase transition from their normal body-centered cubic structure.

There are not many measurements in the infrared on alkali metals. They should behave as free-electron gases in this region, for there is a threshold energy of the order of 1 eV for direct interband absorption. The measurements are difficult, for the reflectance is very high, and one needs great precision and accuracy, of the order of four decimal places in the reflectance. Ellipsometry, using several reflections, has often been used for metals in the infrared, but again the measurement is difficult, for the real part of the ratio of p- to s-polarized electric-field reflection coefficients is very close to one, and the phase shift is very close to 180°. One really needs the difference between the optical properties of the metal and those of a perfect conductor in such cases, and few measurements have been made at wavelengths longer than 2.5 μm for any alkali metal. Intrinsic surface states have been calculated to be present on alkali metals, and to contribute significantly to the infrared optical properties [17–21], in contrast to their contribution in noble metals, for example Ag, where such states contribute effects of only about a part in 10^4. The large predicted effects have not been seen, but there are really no data in the right spectral region on clean samples.

Since there may be interest in infrared optical properties, and the only such measurements do not tie in well with those in the visible, the only option is to use a nearly-free-electron (Drude) model. The parameters in this model may be obtained from data in the near infrared. In the discussion of each alkali metal, we give those parameters that have been extracted from experimental data, but there is considerable scatter in them. The real and imaginary parts of the refractive indices can be obtained from the real and imaginary parts of the Drude dielectric function from

$$2n^2 = +\varepsilon_1 + (\varepsilon_1^2 + \varepsilon_2^2)^{1/2}$$

$$2k^2 = -\varepsilon_1 + (\varepsilon_1^2 + \varepsilon_2^2)^{1/2},$$

with

$$\varepsilon_1 = 1 + \varepsilon_{xx} - \omega_p^2 \tau^2/(1 + (\omega\tau)^2)$$

$$\varepsilon_2 = \omega_p^2 \tau/\omega(1 + (\omega\tau)^2).$$

ε_{xx} is the contribution of high-energy interband transitions to the low-frequency dielectric function, ω_p is the plasma frequency, given in cgs units

by $\omega_p^2 = 4\pi Ne^2/m^*$, with N the number density of electrons and m^* their effective mass. τ is the relaxation time. However, to obtain a good fit to data, τ must be frequency-dependent, in the form

$$1/\tau = 1/\tau_0 + \beta\omega^2.$$

Thus, to characterize the infrared optical properties, we must know four parameters. Note that ω_p and τ_o should give the correct static conductivity, $\omega_p\tau_o/4\pi$. (Sometimes data taken above the lowest interband absorption are fit to a Drude expression. However, in such cases the relaxation time will be different, and the plasma frequency should contain the free-electron mass, or an effective mass closer to it than the infrared value.)

The following critiques, tables, and graphs contain what we consider to be the most useful n and k values for the chosen metals. One of the steps in producing the tables containing E (energy), λ (wavelength), n (index of refraction), and k (extinction coefficient) is to convert E (usually the experimental units in eV) to λ by means of the formula $E\,(\text{eV})\lambda\,(\text{Å}) = 12{,}398.42$. This was done and the values subsequently rounded to those found in the table (usually to four figures). After rounding, however, $E\lambda$ may not give the original conversion factor to four significant figures. Thus, if E from the table is converted to λ using the above conversion factor, the result may not equal the wavelength value in the table and vice versa. This slight discrepancy happens most often in the data taken from Henke *et al.* but should produce no practical problems.

LITHIUM (Li) III

Lithium is a reactive material, and generally only data taken under ultrahigh-vacuum conditions will be mentioned. Li is normally body-centered cubic, but at low temperatures there is a transition to a phase often reported to be hexagonal, a phase with different optical properties. It is the stable phase below about 80 K. However, the phase transition is sluggish, and a low-temperature sample may be a mixture of phases. In fact, the early reports of this transition stated the low-temperature phase was hexagonal close packed [1, 2], but more recent descriptions [3] are 9*R*, a closed-packed stacking that is mixed fcc and hcp. We report only data on the bcc phase. We do not consider data taken in arbitrary units, for example, optical density of a film or electron-energy-loss spectra without suitable normalization, unless those are the only data available in a particular wavelength region. In such a case, we give only a reference to the original work.

The first modern measurements on Li are those of Hodgson [4]. Although the films were not prepared in ultrahigh vacuum, the ellipsometric measurements were made on an Li-silica interface, which remained stable for about a day. The data, taken in the 0.22–2 μm region and at two temperatures, were fit to a free-electron model in the longer-wavelength region. To obtain a good fit, the relaxation time had to depend on frequency. The interband-absorption threshold was not well-defined. Bösenberg [5, 6] made attenuated-total-reflectance measurements on films deposited in better vacuum, using the Li-sapphire interface. His data, covering the range of 2–3.8 eV, are not in good agreement with Hodgson's, but agree better with data taken later by other groups.

Myers and coworkers [7–9] made ellipsometric measurements at the vacuum–metal interface in the range 0.6–4 eV. They evaporated films on several substrates at several temperatures, obtaining different results. There were changes in the spectra with time after deposition. Others (see below) also observed time-dependence. For what was believed to be bcc Li, the first interband threshold was at 2.6 eV. At lower energies, the data were fitted to a free-electron model, but to obtain a fit it was necessary that the relaxation time depend on frequency. Table I lists Drude parameters from several references. Table II lists values of n and k. Figure 1 plots n and k versus μm. Myers and Sixtensson [9] also reported the optical constants of hexagonal Li. Rasigni and Rasigni [10] measured the transmittance of Li films of varying thickness, from which measurements they

extracted the optical conductivity. They covered the 1–6 eV region and found two interband peaks. The one with a threshold at about 2.6 eV was the expected interband peak, whereas the anomalous one peaked between 1.5 and 2.6 eV. Films giving the latter were found to be grainier, either discontinuous grains on the substrate or a distribution of grains on a smoother Li film on the substrate. They made additional studies of the nature of the surfaces of films evaporated on substrates at different temperatures, correlating them with optical spectra [11–15]. They were able to eliminate the anomalous peak in later work [16], in which they give optical constants in the 0.15–10.7 eV range, obtained by Kramers–Kronig analysis of their reflectance measurements in the range 0.5–6 eV [13], and the reflectance of Callcott and Arakawa [17] from 3–10.7 eV. Inagaki *et al.* [18] measured the optical properties of Li in the 0.6–3.8 eV region by ellipsometry on the Li–silica interface. They obtained the anomalous absorption mentioned earlier after allowing their films to stand for a day in UHV, even though their measurements were at the Li–silica interface. The data that they took before the growth of this peak do not agree well with those of Myers *et al.*, but the reflectance calculated from their data agrees with that of Rasigni and Rasigni [13].

The spectra of k from the papers mentioned earlier agree reasonably well, but there are large differences in the n spectra. n has a minimum near 0.5 μm, and the values at this minimum range from 0.13 to 0.21. The data of Rasigni and Rasigni exhibit a local maximum in n at about 0.33 μm not apparent in the other spectra (which end at about 0.33 μm). There are also discrepancies at both ends of the range of these measurements, either in the magnitudes of n, the slopes $dn/d\lambda$, or both. There are no data further into the infrared, and the only data at shorter wavelengths are described in the next paragraph. Of the measurements described in the previous paragraph, only those of Rasigni and Rasigni [16] are close to matching the only data set to shorter wavelengths, and this matching was part of their own data analysis. This does not mean these are the best data, but this matching is the only criterion we can use for having selected them for the table. The data sets are too limited in range to test for consistency by sum rules. Moreover, not all authors report the frequency-dependence of the relaxation time necessary for an extrapolation of their data to longer wavelengths. The discrepancies probably result from differences in samples, either the possible occurrence of two phases, differences in surface roughness, or both. (There may be voids at the Li–substrate interface, which would appear as roughness in measurements made on that interface.)

Callcott and Arakawa [17] determined the optical constants of Li films in the 3–10.7 eV region by multiple-angle reflectance measurements. They worked on the Li–vacuum interface and the Li–substrate (MgF_2) interface, getting agreement in the optical constants only for energies above 6 eV.

Discrepancies below 6 eV were assigned to substrate roughness and structural effects in the film. Below 6 eV, they chose no best set of data, and only results above 6 eV are tabulated.

There are no absolute measurements at energies above 10.7 eV. Haensel *et al.* [19] presented the results of transmission measurements in the 60–149 eV region. They show considerable structure at and above the Li 1s absorption edge, structure that will appear prominently in the k spectrum, but very weakly in that of n.

Extrapolation to the infrared may be made from the Drude parameters, but in the case of Li, those reported are not in good agreement with each other. We list many of them in Table I. (The fact that the effective-mass values are considerably larger than unity is a consequence of the distortion of the Fermi surface mentioned earlier). The first interband transition begins at about 2.6 eV. The Drude parameters may be used to obtain ε_2 for energies below this, but the interband contribution to ε_2 will persist several tenths of an eV below 2.6 eV. Thus, Drude values of n and k would be reliable below about 2 eV, except that a reliable set of parameters cannot be chosen rationally. (Values of the Drude parameters determined from data in the spectral region above the interband absorption are not given in Table I. Such data yield a smaller effective mass, not suitable for extrapolation in the infrared).

We have calculated n and k in the 1.24–240 Å (10,000–51.5 eV) region using the model of Henke *et al.* [20]. The atomic absorption edge is K (55 eV) [21].

We used 8065.48 cm^{-1}/eV to convert among the units of [20], whereas the conversion factor varies by a digit or so for [16]. This should give no problems among the units until the fourth figure.

IV SODIUM (Na)

The optical properties of sodium have been measured with more consistency than those of Li, but the agreement among measurements is still not satisfying. Na is normally body-centered cubic, but it also has a low-temperature hexagonal phase. However, the phase transition sets in at 51 K if aided by plastic deformation, and at 36 K upon simply cooling [1]. This means that evaporated-film samples of Na condensed on substrates at liquid-nitrogen temperatures are probably single-phase films, unlike films of Li condensed under similar circumstances. Na films are similarly likely to be rough, however, and Na is a reactive material.

The first modern measurements on Na were those of Hodgson [2, 3] and Mayer and Heitel [4]. Hodgson made ellipsometric measurements from 0.65 μm to 2.5 μm on the Na–silica interface of films evaporated in less than ultrahigh-vacuum conditions. He reported that his spectra of the optical

conductivity (hence, in this case, of k) were not reproducible from sample to sample, whereas those of ε_1 (essentially n^2) were. This is a similar problem to that encountered in Li. Mayer and Heitel made ellipsometric measurements from 0.3 μm to 2.5 μm on the Na–vacuum interface in ultrahigh vacuum. The real part of the dielectric function was fit to a Drude expression. The imaginary part of the dielectric function, or the optical conductivity, or the k spectrum, exhibited a Drude region and the expected weak interband-absorption threshold at about 2 eV, but there was a lower-energy, temperature-dependent absorption threshold and peak, at about 1.2 and 1.8 eV, respectively. This anomalous peak has proven to be only intermittently reproducible over the years. For example, Payan and Roux [5] found such a peak in Na films, and the peak position depended on film thickness and temperature. Many of the references cited here did not find this peak, although not all carried their measurements to long-enough wavelengths. This peak is discussed in a previous section on alkali metals in general, and we view it here as anomalous, and possibly spurious, despite the extensive theoretical effort it engendered.

Althoff and Hertz [6] made the only measurements to date at wavelengths longer than 2.5 μm, using an ellipsometric method on the Na–NaCl interface over the 2.5–10 μm region. However, their samples were evaporated in vacua of 10^{-6} torr, and their spectra do not agree well with any spectra measured at shorter wavelengths on samples prepared in ultrahigh vacuum.

Smith [7] measured the optical properties of Na films at the Na–silica interface by ellipsometry in the 0.5–4.0 eV spectral region. The interband-absorption threshold was found to be 2.0 eV. Drude parameters were obtained at lower energies. There was no anomalous absorption structure, but the fit to the Drude parameters required a scattering rate that had a term that increased with photon energy, but when plotted as a function of the square of the energy, the expected straight line did not result. Drude parameters are listed in Table I.

Palmer and Schnatterly [8] also used an ellipsometric method on films condensed on sapphire substrates at 77 K. (Other substrates gave rough surfaces that obviously scattered incident light.) They covered the spectral range 1.75–4.5 eV. They also fit ε_1 data to the Drude model. Their optical-conductivity data resembled those of Smith, but agreement was not good in both the Drude and interband regions. They made some measurements at the Na–glass interface. The resultant conductivity spectrum resembled that of Smith more closely in both spectral shape and magnitude. The difference between data at the Na–vacuum and Na–silica or glass interface thus appears to be real, and the explanation is likely to be found in an effective-medium approach to both sets of data. The free surface may be rough to a degree depending on the substrate materials and temperature. The Na–substrate interface may have regions of low density or even

voids between grains nucleated at separate sites.

Monin and Boutry [9] made ellipsometric measurements between 0.24 μm and 0.63 μm on the vacuum–Na interface of films that were condensed at 77 K. They found that upon warming to room temperature, then cooling to 77 K, the optical properties at this temperature had changed irreversibly, evidently due to annealing at room temperature, which led to increased grain size. Their results for both n and k are quite close to those of Smith, although they used the Na–vacuum interface, unlike Smith.

Bösenberg [10] made measurements on the Na–silica interface by attenuated total reflection in the 2–3.8 eV region. His optical-conductivity spectrum does not show much evidence for the expected interband transitions beginning at about 2 eV. Inagaki *et al.* [11] also made ellipsometric measurements on the Na–silica interface in the 0.6–3.8 eV region. Their results are close to those of Smith. Their interband peak in the optical conductivity is somewhat higher and narrower than Smith's.

Sutherland *et al.* [12, 13] made measurements in the vacuum ultraviolet. They first measured spectra of n on the Na–vacuum interface in the region 420–2000 Å by fitting the reflected radiation near the critical angle (n is less than unity in this spectral region) as a function of angle to the Fresnel equations and by using interference fringes in the reflected signal [12]. These data do not scatter much about a curve drawn through them. They then determined the k spectrum of semitransparent Na films from transmission measurements in the region of 2.8–11 eV [13]. At the longer wavelengths, their data are significantly lower than those of Smith and the later data of Inagaki *et al.* Above 6 eV, there is a great deal of scatter in the k spectrum, and its general shape does not interpolate well between the spectra of Smith and Inagaki *et al.* at longer wavelengths, and of Sato *et al.* [14] at shorter.

Sato *et al.* [14] measured the absorption coefficient of Na films in the 10–35 eV region. By assuming n is unity throughout this region, an assumption good to within a few percent in this region [12], they obtained an optical-conductivity spectrum, hence a spectrum of k. We reproduce their values in our tables, but with one exception. Between 30 and 31 eV, there is a sharp absorption edge terminating in two sharp peaks arising from the excitation of the spin-orbit-split $2p$ electrons. We do not reproduce these narrow features in Table II and Fig. 1.

The infrared data of Althoff and Hertz do not match any of the other data in the region of overlap around 2 μm. In particular, at 2 μm there is a jump in the value of k from about 9 in the data of Smith and of Inagaki *et al.* to 11 in the data of Althoff and Hertz. Thus, there are no recommended infrared data, and one must resort to the Drude parameters of Table I. These do not scatter badly, but at increasing wavelength the optical constants calculated from different sets will diverge somewhat. No reliable

values of the scattering time exist, for these have been sample-dependent. Without such data one can calculate only $\varepsilon_1 = n^2 - k^2$. Since $k \gg n$ in this region, one can calculate k but not n from the parameters in Table I. As with Li, Drude parameters determined from data in the ultraviolet are not given below.

In the visible region, we believe the data of Smith and Inagaki *et al.* are the most reliable and physically reasonable. They differ primarily in the height and width of the weak interband-absorption peak in the optical conductivity. We list those of Smith. At shorter wavelengths, the n data of Sutherland *et al.* are listed, but not their k values, which scatter considerably and do not match with other data at either end of their spectral range. At the shortest wavelengths, the k data of Sato *et al.* are listed, assuming n is within a few percent of unity. There are no data at all in the 2000–3000 Å region, and the data sets listed do not extrapolate toward each other satisfactorily across this gap, especially the n spectrum, which has a minimum in the region for which no data exist.

We have calculated n and k in the 1.24–240 Å (10,000–51.5 eV) region using the model of Henke *et al.* [15]. The atomic absorption edges are K (1072 eV), L_1 (63 eV), $L_{2,3}$ (31 eV). Some of these features are indicated in Fig. 1.

We used 8065.48 cm^{-1}/eV to convert between units in [15]. Note that the conversion factors for [7], [12], [14] are slightly different by a digit or two in the fourth significant figure.

V POTASSIUM (K)

Potassium is a reactive metal that does not have a phase transition at low temperature. However, it has a low melting point. Room temperature is adequate for significant atomic motion to take place, which reduces strains at the surface, but may roughen the surface.

The first modern measurements on K were those of Hodgson [1], Mayer and El Naby [2, 3], and Mayer and Heitel [4]. Hodgson made ellipsometric measurements between 0.6 μm and 2.5 μm on the K–silica interface. He

fitted the real part of the dielectric function to a Drude model. The imaginary part varied by about a factor of two from film to film. He did not see the anomalous, low-energy, interband peak reported by Mayer *et al.*, who made ellipsometric measurements on the K-vacuum interface of bulk K samples. Mayer *et al.* fitted the real part of the dielectric function to a Drude expression. The imaginary part, or the optical conductivity, became well-known for many years because of a strong anomalous structure, an apparent interband-absorption peak beginning at about 1 eV, in addition to the expected one, which begins near 2.5 eV. Further discussion appears in the section on alkali metals. We consider the peak anomalous.

Althoff and Hertz [5] made the only measurements to date at wavelengths longer than 2.5 μm, using an ellipsometric method on K–NaCl and K–KBr interfaces over the 2.5–10 μm region. However, their samples were evaporated in vacua of 10^{-6} torr, and their spectra do not agree well with any spectra measured at shorter wavelengths on samples prepared in ultrahigh vacuum.

Smith [6] made ellipsometric measurements between 0.5 and 4.0 eV on the K–silica interface and obtained no anomalous peak. The interband threshold was at 1.3 eV, and the interband-absorption spectrum was in accord with theoretical expectations. Drude parameters were obtained from the data at lower energy. A frequency-dependent scattering rate resulted, but it increased with increasing photon energy faster than the expected second power.

Palmer and Schnatterly [7] also used an ellipsometric method between 1.75 and 4.5 eV on the K–vacuum interface. Their data do not agree well with those of Smith. They did not go to low enough energy to see the interband-absorption threshold.

Yamaguchi and Hanyu [8] made photometric measurements in the 2.07–6.2 eV region on semitransparent films. They measured the transmission and the reflectance from both the K–vacuum and K–silica sides, using polarized radiation and several angles of incidence. Their Drude parameters are listed here. The optical conductivity depended somewhat on sample thickness, but generally was close to that of Smith. The low-energy limit did not permit measurements at the interband threshold.

Harms [9] repeated the measurements of El Naby [3], using essentially the same techniques. The measurements spanned the 0.25–2.5 μm range. He did not find the anomalous peak in most of his measurements, but did detect it when some water vapor had been admitted to the vacuum. His and others' Drude parameters are listed in Table I. The interband conductivity was close to that of Smith; Harm's interband peak was a bit less sharp.

Monin and Boutry [10] made ellipsometric measurements on the K–silica interface in the 2500–6300 Å range. Their lowest energy is not low enough to allow observing the interband threshold, but their data appear

to have a threshold, and certainly a peak, in the interband region much higher in energy than expected and much higher than in Smith's data.

Sutherland and Arakawa [11] measured n in the 3.96–9.69 eV region by the critical-angle method on the K–quartz and K–fluorite interfaces. Sutherland *et al.* [12] measured the k spectrum from transmission measurements of K films on quartz of LiF substrates. They report only a few points between 3.9 eV and 7.1 eV. Their work was superseded by that of Whang *et al.* [13], who covered the 3.3–10.7 eV range. They measured reflectance versus angle of incidence on the K–MgF_2 interface, and transmission of semitransparent films. Their optical-conductivity spectrum matches Smith's fairly well and lies generally somewhat below those of Palmer and Schnatterly, Sutherland, and Yamaguchi and Hanyu. A second interband-absorption structure begins at about 4 eV, and peaks at 8 eV. Its origin is likely to be transitions to d-like states several eV above the Fermi level, but convincing proof is lacking.

Garron [14] showed that surface states may be responsible for some of the discrepancies in the near-infrared data, in particular for differences between data on K–vacuum and K–quartz interfaces. More discussion of these surface states appears in the general section on alkali metals.

Sato *et al.* [15] measured transmission spectra, which give spectra of k under the assumption that n is unity, an assumption valid in the 9.5–32 eV spectral region covered. We tabulate them in Table II, but do not list points close enough together to give a good representation of the $3p$ absorption edge just above 18 eV. The n and k spectra are plotted in Fig. 1.

The data for wavelengths longer than 2.5 μm do not match any data at shorter wavelengths, so for this region it is necessary to extrapolate with the Drude parameters given in Table I. As with Na, this is fairly reliably done for ε_1, which means that the k spectrum can be reliably obtained, but the n spectrum cannot because of the imprecise and sample-dependent values of ε_2 (and, hence, the relaxation time). For the near infrared, visible, and near ultraviolet, we list Smith's data in Table II, which are close to several other spectra reported, as noted above. Further in the ultraviolet, we list the data of Whang *et al.* and Sato *et al.* Unfortunately, Smith's and Whang *et al.*'s data do not overlap. They both end at about 3250 Å, where there is a peak in k and a minimum in n, and there are no data points at these structures.

We have calculated n and k in the 1.24–240 Å (10,000–51.5 eV) region using the model of Henke *et al.* [16]. The atomic absorption edges are K (3608 eV), L_1 (377 eV), $L_{2,3}$ (297, 294 eV), M_1 (34 eV), $M_{2,3}$ (18 eV). Some of these features are indicated in Fig. 1.

We used 8065.48 cm^{-1}/eV to convert among the units of [16], whereas the conversion factor is slightly different for other data in Table II (usually by a digit or two in the fourth figure). This should not present any problems among the units until the fourth figure.

VI CHROMIUM (Cr)

Chromium is a body-centered cubic metal. It is antiferromagnetic below 312 K. The magnetic ordering, the spatial period of which is incommensurate with the period of the crystal lattice, introduces structure in the spectra of the optical constants in the infrared [1–4]. Since the room-temperature phase of Cr is antiferromagnetic, our data include such structure. The ordering is usually multidomained, so bulk anisotropy does not develop. A single domain of antiferromagnetic Cr is slightly tetragonal, not cubic, but the anisotropy is small. Optical anisotropies due to the ordering [2] are

neglected here. One should also note that the type of antiferromagnetism (commensurate or incommensurate) may vary with the content of impurities, especially of other transition metals, and impurity concentrations of the order of 1% may raise or lower the transition temperature by many degrees [2, 3, and references therein].

Cr oxidizes readily, but the overlayer of Cr_2O_3 is continuous and impermeable to Cr or O after a thickness of about 30 Å is reached, and further oxidation does not occur at room temperature. Such an overlayer may affect optical constants in the visible and near infrared obtained by ellipsometry, and by any technique in the vacuum ultraviolet. There have been few studies in which the sample was both prepared and measured in ultrahigh vacuum.

In the visible, near infrared, and near ultraviolet, we report in Table 1 and Fig. 1 the data of Bos and Lynch [3], the result of a Kramers–Kronig analysis of low-temperature absorptance data on bulk samples. They agree well with the room-temperature data of Barker and Ditzenberger [2]. The data of Johnson and Christy [5] are often quoted. They were obtained from reflectance and transmittance measurements on semitransparent films. However, later work [6] showed that these films were rather fine-grained and porous, and new data were obtained on denser, larger-grained films [7]. The reflectance spectrum calculated from these new data agrees well with that derived from the data we quote below, but there are shifts in the individual spectra of n and k.

In the vacuum ultraviolet, we list the data of Olson and Lynch [8]. These data and others in this spectral region [9] may be affected by the presence of an oxide overlayer, but data taken in this spectral region under UHV conditions do not yet exist. In the soft X-ray region, transmission data [10–12] give spectra of k under the assumption that n is unity. The region of the $3p$ absorption edge has been measured. We list the data of Sonntag *et al.* [12].

The measurements of Bos and Lynch extend to 13 μm in the infrared, although their Kramers–Kronig analysis extends further. A number of measurements extend to longer wavelengths [2, 13–21]. These measurements do not agree well with each other, and some of them show weak structures which are probably spurious. Because of this, it is not possible to select long-wavelength data that are reliable. Since Cr is a transition metal, interband transitions occur at arbitrarily long wavelengths, although their strength eventually becomes negligible with respect to the Drude (interband) contribution at wavelengths longer than some value. This appears to be about 20 μm or even longer [22] and makes fits to the Drude model suspect at shorter wavelengths.

We have calculated n and k in the 1.24–240 Å (10,000–51.5 eV) region using the model of Henke *et al.* [23]. The atomic absorption edges are K (5989 eV), L_1 (695 eV), $L_{2,3}$ (584, 575 eV), M_1 (74 eV), $M_{2,3}$ (43 eV), $M_{4,5}$

(2 eV). These features, especially at the lower energies, will be shifted due to the bonding properties of the crystal.

We used 8065.48 cm^{-1}/eV to convert among the units of [23], whereas the conversion factor may be different by one or two digits in the fourth figure for the other data in Table I.

We list below several other reports of quantitative optical spectra for Cr [24–28].

IRON (Fe) VII

Iron is a bcc metal. It has an fcc phase at high temperatures, but we ignore that here. A single domain of cubic Fe that is magnetized is optically anisotropic; the optical dielectric function is a tensor with three independent complex components. However, the anisotropy is small, and we neglect it here. The off-diagonal anisotropy is proportional to the magnetization (M) and the diagonal anisotropy is proportional to its square. Iron is not a highly reactive material, but it is not inert. Several different oxides grow at rates dependent on surface quality, impurities, and ambient conditions.

We do not discuss all of the optical studies on Fe. By and large, the data in the visible and near ultraviolet are in relatively good mutual agreement. The soft X-ray data (k spectrum, since $n \approx 1$) generally agree in shape above the $3p$ absorption edge, but the magnitudes do not, and the discrepancy with the longer-wavelength bulk data is in the wrong direction to be explained by a lower film density.

Values of n and k are given in Table I and plotted in Fig. 1. In the infrared and visible, we list the data of Weaver *et al.* [1]. These were obtained by a Kramers–Kronig analysis of absorptance data on bulk samples. They agree well, where they overlap, with the data of Johnson and Christy [2], obtained from reflectance and transmittance measurements on semitransparent films, which data we report in the ultraviolet. In the vacuum ultraviolet we use the data of Moravec *et al.* [3] obtained from Kramers–Kronig analysis of reflectance data on opaque, thin-film samples. These data show a higher reflectance, and presumably are less affected by oxides. They also match better with the soft X-ray data. At higher energies, we list k spectra obtained from absorption-coefficient measurements on thin films by Sonntag *et al.* [4], using the assumption that n is unity. Their data cover the region of the $3p$ absorption edge, as do those of Wehenkel and Gauthé [5, 6].

Because of the partially filled $3d$ band, interband transitions exist to arbitrarily low photon energies, although at some point they become weak. Jones *et al.* [7] showed that for wavelengths longer than about 10 μm, the interband transitions were negligible. The only infrared measurements that yield spectra of n and k, however, appear to be those of Weaver *et al.* [1], of Lenham and Treherne [8–10], of Siddiqui and Treherne [11], and of Ordal *et al.* [12], from which we list data here. Ordal *et al.* made reflectance measurements to 55.6 μm, although details are not reported, then compared their spectra with others for consistency and fit to a set of Drude parameters. Ordal *et al.* [13] later made measurements in the 33.3–333 μm region, using a resonant cavity. This gives only one measured quantity at each point, but a reasonable approximation allows n and k to be extracted. We list their data in this spectral region.

We have calculated n and k in the 1.24–240 Å (10,000–51.5 eV) region using the model of Henke *et al.* [14]. The atomic absorption edges are K (7114 eV), L_1 (846 eV), $L_{2,3}$ (723, 710 eV), M_1 (95 eV), $M_{2,3}$ (56 eV), $M_{4,5}$ (6 eV). At the lower energies these atomic features may be perturbed by the bonding properties of the crystal.

We used 8065.48 cm^{-1}/eV to convert among the units of [14], whereas the conversion factor may be different by one or two digits in the fourth figure for the other data of Table I.

Finally, we list other references to optical constants of Fe [15–18]. We do not include those that give data only in arbitrary units.

VIII NIOBIUM (Nb)

Niobium is a body-centered cubic metal. It is not highly reactive, but a thin oxide film does form at room temperature, a film that may effect ellipsometric measurements in the visible and near ultraviolet, and all measurements further in the ultraviolet.

There are many sets of near-infrared, visible, and near-ultraviolet data [1–16]. Most of them agree in the number and position of structures in the spectra in the visible and ultraviolet, but there are large discrepancies in the magnitudes of the optical constants. Data taken on films condensed on room-temperature substrates are suspect; heated substrates must be used, and high evaporation rates are necessary to reduce surface roughness [14]. Some measurements were carried out on films prepared in UHV, but the measurements were not made in UHV. There are two vacuum-ultraviolet measurements [8, 17]. The only all-UHV studies were those of Truong *et al.* [17], and of Carroll *et al.* [18]. The former used foil samples heavily annealed in UHV. Unfortunately, their data do not match well at longer wavelengths with any other measurements, although they may be the most reliable to date at shorter wavelengths because of the possible influence of oxides on the other data. Carroll *et al.* worked with an atomically clean single-crystal surface in UHV, but their data are at only seven wavelengths in the 0.40 μm to 0.63 μm region. In this range their *n* spectrum is about 10% higher than that of Weaver *et al.* [8], and their *k* spectrum lies about 4% lower. It is not clear that these differences can be attributed exclusively to surface cleanliness. There is one measurement [19] of optical absorption in the soft X-ray region, the region of the 4*p* excitation, from which a spectrum of *k* can be obtained with the assumption that *n* is unity. However, the sample was a film condensed on a room-temperature

substrate, and its density was probably lower than bulk. The resultant k spectrum is lower than expectations based on longer-wavelength data [8, 17]. Windt *et al.* [20] made multiple-angle reflectance measurements on films to obtain optical constants in the 24–1216 Å region, but all the films were produced *ex situ*.

There are discrepancies in the number and strength of interband transitions in the infrared. In the region below 1 eV, Weaver *et al.* [8] found no peaked structures, although that does not necessarily mean interband absorption is negligible. Golovashkin *et al.* [7] and Kirillova and Nomerovannaya [12] find a number of structures in ε_2 below 1 eV. Rashkeev *et al.* [21] calculated that there is an interband peak at 0.09 eV and a weaker one at 0.3 eV. The calculated peaks were at about the correct positions, but were considerably weaker than the experimental ones.

In Table I we list Weaver *et al.*'s data [8] for the near infrared, visible, ultraviolet, and vacuum ultraviolet. The data of Nestell and Christy [14] and of Lluesma and Aspnes [15] cover a smaller spectral region, but they result in larger values of ε_2, indicative of data less affected by overlayers and granularity or roughness of the sample. We do not list them, for they do not match well with the extant infrared data [7, 8, 12], which should be less sensitive to some of the problems mentioned above. The k spectra we list, then, may be somewhat low in the visible, ultraviolet, and vacuum ultraviolet. We also list the soft X-ray data of Weaver and Olson [19]. Values of n and k are plotted in Fig. 1.

We have calculated n and k in the 1.24–240 Å (10,000–51.5 eV) region using the model of Henke *et al.* [22]. The absorption edges are K (18 986 eV), L_1 (2698 eV), $L_{2,3}$ (2465, 2371 eV), M_1 (469 eV), $M_{2,3}$ (379, 363 eV), $M_{4,5}$ (208, 205 eV), N_1 (58 eV), $N_{2,3}$ (34 eV), $N_{4,5}$ (4 eV). At lower frequencies these features are perturbed by the bonding properties of the crystal.

IX TANTALUM (Ta)

Tantalum is a body-centered cubic metal. It is relatively nonreactive, but a thin oxide layer forms at room temperature, which may affect ellipsometric measurements in the visible and near ultraviolet and all measurements further in the ultraviolet. Very few measurements have been carried out in ultrahigh vacuum, and as for other refractory transition metals, it is difficult to make large-grained films that are of bulk density without condensation on a hot substrate. In common with other transition metals, Ta has interband transitions extending to arbitrarily low energies, making the determination of Drude parameters unreliable.

The near-infrared, visible, and near-ultraviolet data reported to date [1–11] do not agree well qualitatively, although there is agreement on structures. There are only three sets of VUV data [5, 6, 12]. They agree in magnitude, but disagree on the occurrence of a peak in ε_2 at about 8.5 eV. Two transmission studies have been made in the soft X-ray region [13, 14], from which k spectra can be obtained. However, these spectra do not match well any of the spectra from longer wavelengths. The data listed

below for the 20–40 eV region must be considered less reliable than the other data. Finally, Windt *et al.* [15] measured multiple-angle reflectance on thin-film samples prepared ex situ, from which optical constants were derived for the 24–1216 Å region. Ordal *et al.* [16] measured the far-infrared optical properties in the 41.3–413 μm region using a cavity technique. Both optical constants were obtained from a single measurement at each wavelength by using an approximation that should be valid in this spectral region.

We list in Table I the data of Weaver *et al.* [6] for the infrared, visible, ultraviolet, and vacuum ultraviolet. These data were taken on bulk electropolished samples, and were derived by Kramers–Kronig analysis of absorptance measurements at low temperature (longer wavelengths) and room-temperature reflectance measurements (shorter wavelengths). We list the k spectrum in the soft X-ray region derived from absorption (transmission) measurements [14] under the assumption that n is unity. This spectrum does not join well with the higher-energy end of the data from Ref. [6], however. The discrepancy may be ascribable to the effect of an oxide overlayer on the high-energy region of the data of Ref. [6]. The spectra of n and k are given in Fig. 1.

We have calculated n and k in the 1.24–240 Å (10,000–51.5 eV) region using the model of Henke *et al.* [17]. The absorption edges are K (67,417 eV), L_1 (11,680 eV), $L_{2,3}$ (11,156, 9881 eV), M_1 (2708 eV), $M_{2,3}$ (2469, 2194 eV), $M_{4,5}$ (1793, 1735 eV), N_1 (566 eV), $N_{2,3}$ (465, 405 eV), $N_{4,5}$ (242, 230 eV), $N_{6,7}$ (27, 25 eV), O_1 (71 eV), $O_{2,3}$ (45, 37 eV), $O_{4,5}$ (6 eV). At lower frequencies these atomic features are perturbed by the bonding properties of the crystal.

Beryllium* (Be)

E. T. ARAKAWA, T. A. CALLCOTT,† and YUN-CHING CHANG†
Health and Safety Research Division
Oak Ridge National Laboratory
Oak Ridge, Tennessee

Beryllium has many unique properties that make it of both theoretical and practical interest. As a metal, it is strikingly different both from lithium, its neighbor in the periodic table, and the higher Z alkaline-earth metals magnesium and calcium, which occupy the same column of the periodic table. The density of beryllium is not only 3.5 times larger than that of lithium, but is greater than that of magnesium and calcium. Its compressibility is very low, its Debye temperature is among the highest in the periodic table, its melting temperature is much higher than the other alkaline earths, and its electronic specific heat is very low. These properties, and its hexagonal crystalline structure, have generated much theoretical interest in its electronic properties. Several authors have discussed the optical properties of Be expected from theoretical band-structure calculations [1–3].

Beryllium also has many properties that recommend it for exotic optical applications. It is relatively light compared with other metals of optical importance, offers a very high specific stiffness (ratio of Young's modulus to density), a low thermal expansion at cryogenic temperatures, a low Z number, high thermal conductivity, and high reflectivity in the infrared. These properties make it particularly attractive for optical components that are intended for use in space.

In view of its many unique properties, it is surprising that no careful survey of the optical properties of Be has yet been published. In fact, only a few studies have been made, and they have produced widely different results, particularly in the visible region of the spectrum, where the methodology and instrumentation are best developed, and results are

normally most consistent. The variability of results may be traced to the difficulty of sample preparation. Bulk samples are usually produced by high-pressure sintering of microcrystalline powder, which results in the incorporation of significant amounts of BeO in the sample.

For many metals, oxidation problems may be overcome readily by vacuum evaporation, in which the metal evaporates, leaving the more stable oxide behind. In practice, Be is easily evaporated by subliming from the solid state at temperatures of about 900°C, well below its melting temperature at 1278°C. Our own studies suggest that the optical properties depend critically on the evaporation procedure used, and that much of the variability of the results reported in the literature can be traced to sample-preparation problems.

Published studies on the optical properties of Be date from about 50 years ago. Table I summarizes relevant facts about the more significant studies including photon-energy range, sample type, method of measurement, date of publication, and reference number. Note that all the samples in Table I except that listed as single crystal are polycrystalline.

We will discuss the available experimental data in four spectral regions. They are the soft X-ray range (SXR, $\hbar\omega > 50$ eV), the vacuum ultraviolet (VUV, $10\text{ eV} < \hbar\omega < 50$ eV), the infrared–visible–ultraviolet (IR–V–UV, $1\text{ eV} < \hbar\omega < 10$ eV), and the far infrared (FIR, $\hbar\omega < 1$ eV). These regions are chosen not to match the standard definitions of these regions, which in any case are very vague, but for convenient discussion of the available results.

Normal-incidence reflectance data for the three lowest-energy spectral regions are shown in Fig. 1. The wide range of results in the available literature is apparent, and will be the subject of further discussion. The reason for the above division into four spectral regions is also apparent. Above 10 eV, the reflectance makes the transition from reflecting to transmitting behavior at the plasmon energy. Between 1 and 10 eV, absorption by interband transitions reduces the reflectance and introduces prominent structure. Below 1 eV, the rising reflectance indicates a transition to free-electron metallic behavior.

In the SXR spectral region (>50 eV), the photon energy is above the plasmon energy (18.4 eV), and most of the interband oscillator strength is exhausted. Consequently, Be is weakly absorbing so that $n \cong \sqrt{\varepsilon_1} \approx 1$ and $\varepsilon_2 \simeq 2k \ll 1$. The only important physical process affecting the optical properties is the onset of absorption at the Be K-edge at 109 eV. The data available in this region are from thin-film transmittances that provide a measure of the linear absorption coefficient, $\mu = 4\pi k/\lambda_0$, where λ_0 is the wavelength of the incident radiation. The available measurements are reported in Refs. [4–7]. The measurements reported by Henke and Elgin [5] and Barstow *et al.* [6] are consistent with each other.

In the VUV spectral range (10–50 eV), the major feature of the spec-

trum is the transition from reflecting to transmitting behavior at the plasma energy (18.4 eV). Reflectance data from Seignac and Robin [8] and Toots *et al.* [9] are plotted in Fig. 1. Both sets of data were obtained on films with thickness 300–1000 Å evaporated on glass substrates and measured in vacua of 10^{-7} to 10^{-10} torr.

The reflectance data in the 1–10 eV range from Seignac and Robin [8], Hunderi and Myers [10], Weaver *et al.* [11], and Hull [12] are also plotted in Fig. 1. The most striking feature in this region is the wide range of reflectances obtained from careful studies in a spectral region where the procedures of optical measurements are usually most reliable. The two reflectance curves reported by Weaver *et al.* for the electric-field vector parallel ($E \| c$) and perpendicular ($E \perp c$) to the c-axis direction, were obtained on single-crystal surfaces prepared by mechanical polishing, with a subsequent chemical etch. These values are represented by the symbols (+) and (□), respectively. The reflectance data of Hull [12] were taken on the carefully polished surface of a polycrystalline mirror blank prepared by pressure sintering a low-oxygen-content (<0.5%) Be powder. This surface, intended for use as a reflector in the infrared, gives one of the highest reflectances for Be reported to date in the FIR region. However, this surface shows lower reflectance than the best evaporated films in this spectral region.

The highest reflectances reported in the visible were obtained by Seignac and Robin on Be films prepared by slow evaporation in ultrahigh vacuum (UHV). Because of the careful UHV-preparation techniques used, and because most sample preparation problems tend to reduce the measured reflectance, our initial assessment was that these data were the best available. A series of experiments performed in our laboratory confirm this initial judgment. We have been able to identify film-preparation procedures that result in lower reflectances. Thus, we adopt the reflectance values of Seignac and Robin as the best available in this spectral region. It should be noted that the reflectance values of Hunderi and Myers are substantially the same in the region of overlap. Hunderi and Myers' results are for evaporated films on sapphire prepared and measured in a vacuum of 10^{-10} torr.

Values of n and k in the visible region have been obtained by Seignac and Robin and Hunderi and Myers. Although the reflectances are very similar, there are substantial differences in the values of n and k. Of particular significance is the crossing in the values of n and k in the spectral region between 1.7 eV and 3 eV in the data of Seignac and Robin, which results in the value of ε_1 exceeding zero over this range. Our own ellipsometric measurements on evaporated films in this spectral range confirm the crossing of the n and k values reported by Seignac and Robin.

The large range of reflectance values observed for samples in the visible and ultraviolet is not unprecedented. An equally large range of reflec-

tances has been reported for aluminum, depending on the method of film preparation (evaporation in UHV or normal vacuum, sputtering or mechanical polishing) [13]. It is well-known that rough surfaces not only scatter, but can couple incident light to surface-plasmon modes and reduce the reflectance [14]. It seems probable that the sensitivity of the reflectance to surface structure, and perhaps to bulk grain size, is related to coupling of light to surface- and/or bulk-plasmon modes in these samples.

In the FIR spectral region (<1 eV), Shklyarevskii and Yarovaya [15] report a full set of optical constants, and other workers [12, 16, 17] have obtained normal-incidence reflectance data. The reflectances obtained by Shklyarevskii and Yarovaya are low, which we believe to be evidence for poor film structure. The reflectances of Hull's polished bulk samples [12] are among the highest reported for this spectral region. We have measured the optical constants by ellipsometry for a number of samples in the transition region from 3 eV to 0.6 eV, and normal-incidence reflectance from 3 eV to 0.1 eV. In general, it appears that in the FIR, as in the visible region, the best samples have the highest reflectance.

From the sources described in previous paragraphs, optical constants are available that span the spectral region up to 26 eV, although only normal-incidence reflectance data are available for most of the far-infrared region. We have obtained a consistent set of optical response functions for the entire spectral range by assembling a normal-incidence reflectance $R(0)$ curve for energies of $0.06\text{ eV} < \hbar\omega < 26\text{ eV}$ from published results, extending it to zero and infinite energies using appropriate analytic functions, and performing a Kramers–Kronig (K–K) analysis on $R(0)$. The reflectance values used were obtained by drawing a smooth curve through the following data sets:

$$0.06 < \hbar\omega < 0.8\text{ eV}\ [12];$$

$$0.8 < \hbar\omega < 5.0\text{ eV}\ [10];$$

$$1.5 < \hbar\omega < 14\text{ eV}\ [8];$$

$$14 < \hbar\omega < 26\text{ eV}\ [9].$$

In regions of overlap, higher reflectance values were favored. These data sets are shown along with the fitted $R(\hbar\omega)$ curve in Fig. 1.

Below 0.06 eV, the reflectance was extrapolated to zero energy using a linear extrapolation of Hull's data. Above 26 eV the reflectance was extrapolated to infinite energy as $\hbar\omega^{-4}$, in accordance with the behavior of nearly-free-electron metal above the plasma edge. Reliable n and k values

could be obtained only up to 25 eV from this analysis. To obtain the optical constants above 25 eV, a second K–K analysis was carried out using the k values from zero to 25 eV derived above, together with the experimental k values of Henke (60–250 eV) and Barstow (41–705 eV). The structural features from 110 eV to 130 eV just above the K edge were derived from the absorption data of Sagawa [18]. The k values from 15 eV to 25 eV together with the experimental values from 60 eV to 190 eV were found to fit the relation $k \propto E^{-3.3}$. This relationship was used in the region of 25–60 eV where no values were available. The k values above 160 eV were found to fit the relation $k \propto \hbar\omega^{-3.33}$. This analytic function was used in the high-energy extrapolation required for the K–K analysis. Finally, the initial K–K analysis on the normal-incidence reflectance $R(0)$ was refined slightly by using a high-energy extrapolation of $R(0) \propto \hbar\omega^{-4.7}$ as found from the behavior of $R(0)$ derived in the second K–K analysis of k. The results of these analyses are likely to be least reliable in the FIR spectral region. For example, an error of ± 0.005 in the measured reflectance in this region changes the k values by only a few percent but changes the n values by 20–30%.

The n and k values derived from the K–K analysis are plotted in Fig. 2 and a numerical printout is given in Table II. These values are a combination of the results from the two types of K–K analyses. The values from 0.02 eV to 20 eV and from 26 eV to 300 eV were those derived in the analyses of $R(0)$ and k, respectively. The k values from 20 eV to 26 eV are the same in both sets of data, whereas the n values are a smooth joining of the two data sets.

The n and k values derived from the K–K analyses agree well with the values given by Seignac and Robin for 2–26 eV and those given by Toots *et al.* for 10–28 eV. The k values from 0.6 eV to 2.5 eV agree with Hunderi and Myers' values, while the n values differ somewhat. In general, the optical constants derived here for polycrystalline Be are believed to be accurate to $\pm 20\%$ over the whole energy region.

Also included here as Table III are the n and k values from 299 eV to 10,000 eV derived from the latest Henke-model scattering data [19]. Henke *et al.*'s values agree well with those in Table II in the region of overlap from 200 eV to 300 eV.

Cobalt (Co)

L. WARD
Coventry Polytechnic
Coventry, England

Cobalt is an element with an atomic number of 27 and is one of the group of transition metals; it can readily be obtained in the form of blocks, rods, or powder, and its most common impurities are iron, nickel, sodium, and potassium. There are two allotropic forms of cobalt: close-packed hexagonal, which is stable at room temperature, and face-centered cubic, which is stable above 417 °C and which can be produced from the hexagonal form by a suitable annealing procedure. Much of the published work on solid cobalt refers to the hexagonal close-packed crystal structure, which implies that the optical properties should be different along different crystal directions. However, in most cases, authors have dealt with polycrystalline material, where the optical properties are independent of direction; only one set of results has been published for single-crystal bulk cobalt in which the optical properties along both the main crystal axes are considered. In addition, several papers have reported measurements on thin films, again mostly in the polycrystalline form.

Being metallic, cobalt, at long wavelengths in the infrared region, may be expected to behave according to the classical Drude formulas for free-electron materials, namely,

$$\varepsilon_1 = n^2 - k^2 = 1 - A\nu_c/2\pi(\nu^2 + \nu_c^2)$$

$$\varepsilon_2 = 2nk = A\nu_c^2/2\pi\nu(\nu^2 + \nu_c^2),$$

where A is a constant, proportional to the dc electrical conductance, ν is the frequency and ν_c is the electron collision frequency. These formulas predict that in the infrared the optical constants n and k should have large values with both increasing with wavelength. This behavior is in fact observed at all wavelengths longer than about 6 μm, but below that point, there is a marked departure from the Drude equation in the form of increases in the values of both n and k as the wavelength decreases, producing maxima in each at about 3 μm. It is generally regarded that this

anomaly is caused by the onset of interband electron transitions due to the very small energy gap (0.20 eV) between the Fermi level in the almost full d-band and the next higher s-band. However, as the wavelength continues to decrease below 1 μm, n and k resume their downward trend in values and ultimately n becomes equal to k, which is the condition for plasma oscillations; this plasma resonance occurs at a frequency of $18.6 \times 10^{14}\, s^{-1}$ (0.16 μm). At very short wavelengths, n becomes asymptotic to unity, while k continues to fall, reaching extremely low values below 0.01 μm. However, there are further maxima in k, one at 0.020 μm and a second at 0.011 μm. These are due to additional electron transitions between inner levels, the first at the $M_{II,III}$ point and the second at the M_I point. Beyond this wavelength, there is little published experimental optical information on cobalt, so further interband transitions have not been recorded, although X-ray data indicate L-edges at 0.0016 μm and 0.0013 μm and a K-edge at 0.00016 μm [1].

Much of the work on the optical properties of metals published before about 1950 is now regarded as unreliable because of the uncertain state of the surfaces used. Not only does mechanical polishing produce an atypical surface layer in which the crystal structure is broken down and much dislocated, but many crystals rapidly become oxidized or contaminated when exposed to air; this produces a surface layer having unknown optical properties, of which it is consequently difficult to take account when calculating n and k. Two developments since 1950 have led to the production of reliable, clean, and reproducible crystalline surfaces, suitable for optical work: ultrahigh-vacuum conditions can be generated, which almost eliminate oxidation problems and at the same time create the conditions under which epitaxial films can be deposited; and mechanical polishing can be carefully controlled or replaced by electrochemical polishing, so that deep-seated mechanical damage may be avoided. Archard [2] has given a review of modern polishing techniques.

There have been two major reviews covering the optical constants of the transition metals, including cobalt. The first, by Weaver *et al.* [3], surveyed a large number of papers including those by Kirillova and Charikov [4], Lenham and Treherne [5], Yu *et al.* [6], Sonntag *et al.* [7], Johnson and Christy [8], Weaver *et al.* [9] and Wehenkel and Gauthe [10]. Making use mainly of their own results on single-crystal hcp cobalt, Weaver *et al.* [3] have presented sets of data of n and k over the wavelength range 0.15–12.44 μm for the two cases of the electric field vector of the incident radiation parallel to and perpendicular to the c axis of the crystal, that is, the axis at right angles to the base of the hexagon. In the second review, Ordal *et al.* [11] collected data for cobalt over a wide range of wavelengths from 0.20–20 μm, mainly in the infrared region. The main sources of their data were Johnson and Christy [8], Weaver *et al.* [9], and Kirillova and Charikov [4]. As well as giving tables of values of n and k between 0.19 μm

and 20.0 μm, they have graphed ε_1 and ε_2 against wave number. A further, later review by Ordal *et al.* [12] continued the same work in the infrared and showed graphically a Drude-model fit to the various experimental results.

Values of n and k for cobalt from various sources are given in Table I and graphed in Fig. 1; the wavelength range covered is 6×10^{-4}–12.4 μm and, wherever possible, slight wavelength overlaps have been included between the different sets of results.

Results for X-ray Region

For extremely short wavelengths in the X-ray region (6–120 Å), there are no direct experimental results for the optical constants of cobalt. However, Henke [13] has shown that n and k in this wavelength region may be calculated from the X-ray scattering coefficients of the atoms involved. Thus, for cobalt:

$$k = 40.0\lambda^2 f_2$$

$$n = 1 - 40.0\lambda^2 f_1,$$

where λ is the wavelength in microns and f_1 and f_2 are the appropriate scattering factors. Henke *et al.* [14] have published tables of f_1 and f_2 for many values of wavelength and photon energy for some of the atoms in the periodic table, from which the values of n and k for cobalt at these wavelengths have been calculated; these are tabulated at the end of this article in Table I. As expected, n in this region of the spectrum is close to unity, whereas k shows a definite peak at 16 Å (0.0016 μm) due to the $L_{2,3}$ transitions, and a much smaller peak at 0.00134 μm due to the L_1 transition.

Results for Cobalt Films

At slightly longer wavelengths (0.004–0.06 μm) experimental values of the absorption coefficient, α, equal to $4\pi k/\lambda$, have been published by Sonntag *et al.* [7] and also by Wehenkel and Gauthe [10, 26]. Sonntag *et al.* used synchrotron radiation in a direct measurement of the absorption coefficient; k may be easily deduced from the graphs they provide. It is assumed that n is approximately equal to unity in this spectral region. Wehenkel and Gauthe measured the electron-energy-loss spectrum by bombarding thin films of cobalt by 35 keV electrons; a Kramers–Kronig summation technique was then used to calculate ε_1 and ε_2, from which n and k can be extracted. Both these studies revealed a maximum in k at 0.020 μm and a shoulder at 0.011 μm (62.3 eV and 107 eV); these are due to the transitions $M_{II,III}$ and M_I, respectively. The values of k deduced from

Wehenkel and Gauthe are larger than those from Sonntag *et al.*, particularly at the shorter wavelength end. Values of k from both sources are presented in Table I, those of Sonntag *et al.* from 0.006–0.03 μm and the ones from Wehenkel and Gauthe between 0.035 μm and 0.31 μm. There is some wavelength overlap between these results and those calculated by Henke's method, and the agreement in the values of the optical constants is considered to be satisfactory. Fanfoni *et al.* [15], studying the electron-energy-loss spectrum up to 240 eV (0.005 μm), confirmed the $M_{II,III}$ edge at 0.018 μm but did not discover any further edges beyond that point, although a peak might have been expected at 0.011 μm.

A set of results produced by Yu *et al.* [6] is considered to be very reliable; they used specimens of polycrystalline cobalt prepared by electron-beam evaporation under ultrahigh-vacuum conditions. The optical parameter measured was the reflectance near normal incidence, and the optical constants were extracted by Kramers–Kronig analysis over the range 0.1–25 μm, although they give useful graphs only for energies greater than 0.25 eV, that is, wavelengths less than 5.0 μm; these values of n and k have also been tabulated in Table I and link reasonably well with those of Wehenkel and Gauthe.

Johnson and Christy [8] give a set of values of n and k between 0.64 eV and 6.60 eV (0.2–2.0 μm), their results being obtained from measurements of the reflectance and transmittance of thin evaporated films having thicknesses between 200 Å and 500 Å. In general, their values of both n and k, which are presented in Table I, were smaller than those reported by Yu, possibly either because of the vacuum conditions prevailing in their equipment or the different substrate temperature used during evaporation.

Viguier *et al.* [16], using both ellipsometric and reflectance measurements, have produced values of ε_1 and ε_2 for polycrystalline cobalt films 1000 Å thick between 1 eV and 5 eV (0.25–1.25 μm). There were no distinctive optical features over this region; ε_2 was positive and increased steadily with wavelength, whereas ε_1 was negative and became more so as the wavelength increased. An accuracy of 0.2% was claimed for measurements in the visible spectrum, the greatest uncertainty being due to the surface roughness. However, the calculated values of n and k from this work are both at least 10% smaller than those given by Johnson and Christy. A set of their results is included in Table I, since this is one of the most recent determinations of the optical constants of cobalt.

Kudryavtsev and Lezhnenko [17] investigated cobalt films between 1 μm and 13 μm in both the hcp and the fcc crystal forms, changing from one form to the other by suitable annealing above 400 °C. Experimentally, Beattie's method [18] was used, in which the phase change on reflection was measured for several angles of incidence, which in this case were greater than 80°. The authors noted significant differences between the optical properties of the two forms of cobalt in both the intra- and

interband transition regions. In the interband region ($\lambda > 6$ μm) n increased while k decreased on changing from hexagonal to cubic, whereas in the interband region ($1 < \lambda < 6$ μm) both n and k decreased for a similar change. Because their set of results for the cubic form of cobalt is virtually unique, it has been included in Table I.

Clemens and Jaumann [19] measured the optical constants of evaporated layers of cobalt having thicknesses of about 0.03 μm and deposited on glass substrates; the wavelength range covered was 0.42–2.5 μm. The special feature of this work was that the films were magnetically saturated at right angles to their plane, and measurements were made of the reflectances and transmittances from both sides of the substrate. Both n and k turned out to be different as determined from the two sides, but those from the air side agreed well with the results of Weaver *et al.* [3] for the extraordinary ray. Over the spectral region investigated, both sets of optical constants increased steadily with wavelength; from the published graphs, n and k can be read to about ± 0.01.

Results for Bulk Cobalt

Kirillova *et al.* [20] measured the reflectance of polycrystalline solid specimens between 0.1 μm and 0.25 μm and then used Kramers–Kronig analysis to extract ε_1 and ε_2. They noted the effects of the first quantum absorption band between 0.2 μm and 1.2 μm due to electron transitions in various directions within the Brillouin zone. However, the graphs they give are not suitable for the accurate reading of n and k values. Kirillova and Charikov [4] studied bulk polycrystalline cobalt by a polarimetric technique between 2.5 μm and 20.0 μm, noting the contribution from interband transitions in this region even up to 6 or 7 μm. They calculated the plasma frequency to be $18.6 \times 10^{14} s^{-1}$ (that is, the plasma wavelength = 0.162 μm) and the electron relaxation frequency as $2.5 \times 10^{14} s^{-1}$. Bolotin *et al.* [21] obtained the optical constants for a mechanically polished and then annealed polycrystalline specimen of cobalt using the method of Beattie [18]; values of n and k were tabulated between 0.3 μm and 17.0 μm. The classical free-electron theory provided a satisfactory model between 6 μm and 17 μm, but at shorter wavelengths the anomalous behavior described above was observed, there being a peak in the electrical conductivity at 1.5 μm. The values of k reported by this group were in approximate agreement with those of Yu, but those for n were considerably lower, particularly at the shorter wavelengths investigated, again probably because of the damage to the surface layer by the mechanical-polishing technique employed. However, because they are still one of the few sets of data covering this wide wavelength band, they are quoted in Table I. Afanasyeva and Kirillova [22] give data measured on polycrystalline cobalt between 0.8 μm and 3.5 μm. Using mechanically polished specimens, the measured parameter was the electrical conductivity, which as shown above

is closely related to the optical constants. They also paid particular attention to the spectral region where n increased as the wavelength decreased. Their values for k were comparable with those of Bolotin *et al.*, but the data for n were significantly smaller, particularly at the shorter wavelengths, perhaps due to their polishing technique. Other sets of data for the infrared region (0.3–12.5 μm) have been obtained by Lenham and his collaborators [5, 23], who used an ellipsometric technique in conjunction with mechanically polished polycrystalline specimens. Their published graphs, however, are not generally suitable for the extraction of accurate values. A set of values of n and k for bulk cobalt at different temperatures has been published by Gushchin *et al.* [24]. Beattie's method was again the experimental method used, and the measurements were carried out between 0.4 and 3.3 μm and at temperatures of 20, 1400 and 1600 °C. The results at 20 °C are in fair agreement with those of Bolotin *et al.* taken at the same temperature, and it was also observed that both n and k increased with temperature up to 1400 °C. The optical constants at 1400 °C are included in Table I. Kulikov and Kulatov [25] report an interesting theoretical study of the variation of the optical properties of cobalt with pressure.

Results for Cobalt Using Polarized Radiation

Weaver *et al.* [9] present detailed tables of the optical constants of single-crystal cobalt between 0.15 and 12.4 μm for radiation polarized with its **E** vector parallel to and perpendicular to the c axis, that is, the axis at right angles to the base of the crystalline hexagon; these being the only data to deal with both states of polarization, they are quoted extensively in Table I. Their measurements were made on electrolytically polished specimens employing reflectance for wavelengths below 0.3 μm and calorimetry for wavelengths greater than 0.3 μm. The two sets of values exhibit their greatest differences at the longer wavelengths investigated (1–6.5 μm), where n for $\mathbf{E}_{\parallel c}$ (n_e) is smaller than that for $\mathbf{E}_{\perp c}$ (n_o); the opposite applies to the values of k where k_e is larger than k_o. For wavelengths below 0.6 μm, the separate values of n and k converge. At this point, the values of the optical constants are also in good agreement with those produced by Yu *et al.* and Bolotin *et al.* for the polycrystalline form of cobalt, as would be expected to happen. The results of Weaver *et al.* for the cases of polarization both parallel and perpendicular to the c axis indicate maxima in n at 1.7 μm and corresponding minima at 6 μm. For k there is a maximum at 1.35 μm (perpendicular c axis) and a much less well-defined maximum at 1.40 μm (parallel c axis).

Università di Pavia
Pavia, Italy

Graphite is a semimetal with uniaxial layered crystalline structure and is characterized by two different dielectric functions, $\tilde{\varepsilon}_\perp$ and $\tilde{\varepsilon}_\parallel$. They correspond to the electric-field vector **E** perpendicular ($\tilde{\varepsilon}_\perp$) and parallel ($\tilde{\varepsilon}_\parallel$), respectively, to the c axis (symmetry axis, perpendicular to the basal plane). Therefore, $\tilde{\varepsilon}_\perp$ measures the ordinary (o) while $\tilde{\varepsilon}_\parallel$ the extraordinary (e) ray properties. Since the cleavage plane is perpendicular to the c axis, $\tilde{\varepsilon}_\perp$ can easily be determined, for example, by normal-incidence reflectance measurements. $\tilde{\varepsilon}_\parallel$ cannot be obtained in a similar way, because of the difficulty of preparing suitable optical surfaces parallel to the c axis.

Small, soft flakes of natural graphite are found in various rock formations, but relatively little work has been done on these crystals, since they are generally quite impure, highly twinned, and rather difficult to handle [1, 2]. After 1958, it was established that massive coherent deposition of carbon can be produced by the pyrolysis of carbonaceous vapor on a suitable substrate at temperatures of the order of 2000°C. This material, called pyrolytic graphite, consists of many small crystallites with random orientation about the c axes, but with varying degrees of misorientation of c axes. Successively, it was found that highly oriented (HO) material (c axes aligned to within 0.2°) could be obtained if pyrolytic graphite was annealed at very high temperatures (~3000°C), particularly under applied stress [3]. HO pyrolytic graphite exhibits characteristics very similar to high-purity, natural, single crystals: in particular, their reflectance spectra coincide within experimental accuracy [3, 4]. This fact allowed the optical functions of graphite to be obtained mainly on HO pyrolytic material.

Graphite has aroused great interest from both fundamental and technological points of view, and various attempts have been made to study, experimentally and theoretically, its optical and dielectric functions [4–26]. Nevertheless, the experimental data are not yet complete and show

disagreement among themselves. Overlooking the differences inherent in the techniques used (optical, photoemission, EELS), this disagreement is due to the aforesaid difficulty in obtaining good surfaces parallel to the c axis, and to the fact that all optical data have been derived from reflectivity (R) measurements (at near-normal incidence, with subsequent Kramers–Kronig (K–K) analysis, or as a function of angle of incidence, using the Fresnel relations). Therefore, the scattering among data can be explained by errors connected to K–K analysis; the difficulty of obtaining absolute values of reflectivity, particularly at large angles of incidence; and the different surface conditions affecting R. The room-temperature values of n_o, k_o and n_e, k_e tabulated in Table I and shown in Fig. 1, were obtained from the following works and references therein: Klucker [17] from 40 eV to 5 eV; Venghaus [21] for n_e and k_e obtained by EELS, in the 18–2 eV range, where they substantially differ from optical data; Greenaway *et al.* [5] from 5 eV to 2 eV; Guizzetti and Piaggi [26] who K–K-transformed R spectra from Refs. [5, 17, 22] from 2 to 0.02 eV for n_o and k_o only.

Klucker *et al.* [17, 18] measured R of freshly cleaved samples (c axis perpendicular to the surface) of pyrolytic graphite between 3 eV and 40 eV for different angles of incidence. The synchrotron radiation was polarized either parallel or perpendicular to the plane of incidence, with a degree of polarization between 0.9 and 0.97. The spectral resolution was better than 6 Å. Relative and absolute R measurements were performed. The ratios of the reflectances for nine angles between 15° and 75°, in steps of 7.5°, were determined in the relative measurements. $\tilde{\varepsilon}_\perp$ and $\tilde{\varepsilon}_\parallel$ were then derived simultaneously by least-squares fitting R with Fresnel's formula for anisotropic uniaxial crystals. Absolute R at near-normal incidence (15°) was used to determine $\tilde{\varepsilon}$ by K–K analysis. The asymptotic behavior $R(\omega) \propto \omega^{-4}$ was assumed for energies above 40 eV, whereas the R data from Greenaway *et al.* [5], Boyle and Nozières [6], and Sato [10] were used below 3 eV. Absolute R was in good agreement with R calculated from relative measurements. Moreover, the gross features in the R spectrum for $E \perp c$ generally agreed well with previous spectra in [4, 5, 8] and those derived from EELS [13, 14, 21]. Two major differences were observed above 8 eV. First, the extrapolated reflectance of Taft and Philipp [4] above 25 eV, which is important for K–K analysis, was significantly lower. Second, the reflectance calculated by Zeppenfeld [14] and Venghaus [21] from EELS was lower and did not show the sharp structure between 15 and 16 eV. These differences obviously were manifested in the spectra of $\tilde{\varepsilon}_\perp$, mainly in their absolute magnitudes and in some fine structures. More significant differences occur in $\tilde{\varepsilon}_\parallel$ among results from optical measurements, EELS, and theoretical calculations, in both the overall spectral behavior and the absolute magnitude below 15 eV. In particular, EELS data [14, 21] produce a peak at 11.4 eV in $\tilde{\varepsilon}_\parallel$, which is totally absent in the Klucker *et al.* [18] spectrum. This peak is several times larger than the

estimated uncertainty in the optical spectra, which is relatively large in this region, due to uncertainty in the degree of polarization.

The electron-energy-loss spectrum was measured by Venghaus [21] on stripped pyrolytic-graphite samples about 1000 Å in thickness. The experimental conditions were as follows: 60 keV energy of the primary electrons, with 0.4 keV halfwidth in the energy distribution; 10^{-3} rad scattering angle; 70° angle between the c axis and the direction of incoming electrons to determinate $\mathrm{Im}(-1/\tilde{\varepsilon}_{\parallel})$. Corrections for double-scattering and for $\tilde{\varepsilon}_{\perp}$ were included in the calculation of $\tilde{\varepsilon}_{\parallel}$. The resulting $\tilde{\varepsilon}_{\parallel}$ was in very good agreement with that obtained by Zeppenfeld [14]. In particular, a detailed discussion of uncertainties in the energy-loss function and in the K–K analysis led Venghaus [21] to conclude that the maximum in $\varepsilon_{2\parallel}$ near 11 eV was established beyond experimental and computational errors. No conclusive evidence in favor of or against a strong transition at ~11 eV has been provided by band-structure calculations [5, 13, 19], due to uncertainty in the calculated gaps and to the difficulty in correlating structures in the loss spectrum to specific interband transitions. Due to a lack of other evidence that could resolve the problem, we have tabulated $n_{\parallel}$ and $k_{\parallel}$, in the 2–18 eV range, both from optical and EELS measurements.

Greenaway *et al.* [5] measured reflectance of both natural and pyrolytic-graphite single crystals in the visible and UV regions. Samples of pyrolytic graphite, annealed at 3600 K, were prepared with a polished face perpendicular to the cleavage planes, by careful cutting and mechanical-polishing techniques. No etching procedure were attempted. The surface area of these samples (>1 cm^2) and the high degree of flatness permitted accurate R measurements with incidence angle as high as 88°. Laser light at three different wavelengths (4579 Å, 5145 Å, 6328 Å) yielded good absolute R values, to be used as reference and to check that no significant differences existed between the optical properties of natural and pyrolytic graphite. The reflectance R_s and R_p, corresponding to the electric field perpendicular or parallel to the plane of incidence, respectively, were measured from 1.9 to 5.15 eV at incidence angles from 10° to 80° in steps of 10°, as well as at 75°, 85°, and 87°. For small angles the results agreed well with those of Refs. [4, 18] taken at near-normal incidence. The same excellent agreement was obtained in [5] from 0.3 to 11.5 eV R on cleaved natural graphite. In addition, Greenaway *et al.* [5] measured R in the 2–9 eV range at near-normal incidence on polished surfaces both parallel and perpendicular to the c axis. R spectra of polished surfaces were not suited for deriving the optical constants through K–K transforms due to their inferior quality with respect to the cleaved surfaces; they are useful only in comparing data for $E \perp c$ and $E \| c$ under identical surface conditions. The optical constants $n_{\perp}$, $k_{\perp}$ and $n_{\parallel}$, $k_{\parallel}$ from 0.9 to 5.15 eV were obtained by a least-squares fit of R_s and R_p at different incidence angles with the Fresnel relations for uniaxial materials. The values of $n_{\perp}$ and $k_{\perp}$ were in close agreement (±10%) with

those of Taft and Phillip [4] obtained from K–K analysis, and with those of Klucker *et al.* [18]. We note that $n_{\parallel}$ and $k_{\parallel}$ show no structures in this region ($k_{\parallel} \approx 0$), in agreement with data of Ergun [9]. However, this is in contrast with optical properties of graphite calculated by Johnson and Dresselhaus [15], who predict a lower reflectivity with a peak near 4.3 eV. They attributed this discrepancy to experimental difficulties, for example, a slight depolarization of the light in both Greenaway *et al.*'s and Ergun's experiments [5, 9].

Guizzetti and Piaggi [26] derived $n_{\perp}$ and $k_{\perp}$ below 2 eV by K–K transforming R spectra, at near-normal incidence, of Klucker [17], Greenaway *et al.* [5], and Nemanich *et al.* [22], which showed the best agreement among themselves. Moreover, the infrared R values of Nemanich *et al.* [22] were much higher than those reported by Boyle and Nozières [6], Sato [10], Misu *et al.* [23], and Bowers *et al.* [24]. The extrapolation $R(\omega) \propto \omega^{-p}$ was used above 40 eV. Two different values of the exponent p were used. In one case the usual value $p = 4$ was assumed. In the other case p was adjusted to reproduce the values of $n_{\perp} = 2.91$ and $k_{\perp} = 1.71$, measured with an ellipsometer working at $\lambda = 6328$ Å. Although the resulting value of p is 3.4, $n_{\perp}$ and $k_{\perp}$ values below 2 eV differ only by 1% from the previous ones, which are tabulated here.

Nemanich *et al.* [22] measured IR reflectivity of HO pyrolytic graphite for $E \perp c$ on a cleaved surface parallel to the layers and for $E \| c$ on a polished surface cut perpendicular to the layers. The surface damage incurred in the polishing step was accounted for by scaling the $E \| c$ spectrum with the ratio of two $E \perp c$ spectra, obtained from a cleaved and a polished surface, respectively. The $E \perp c$ spectrum exhibits a sharp weak structure at 1587 cm^{-1} (attributed to the "in-plane" E_{1u} symmetry vibrational mode), superimposed on a background reflectance rising slowly with decreasing frequency. The $E \| c$ spectrum displays a sharp weak structure at 868 cm^{-1} (attributed to the "out-of-plane" A_{2u} symmetry mode) on a constant background. These structures were well fitted by the classical oscillator model, which yields the complex dielectric function

$$\tilde{\varepsilon} = \tilde{\varepsilon}_{\infty} + \frac{S\omega_T^2}{(\omega_T^2 - \omega^2 - i\Gamma\omega)},$$

where ω_T is the phonon frequency, Γ is the phenomenological damping constant, S is the oscillator strength, and $\tilde{\varepsilon}_{\infty}$ is the complex dielectric function resulting from electronic transitions. In the range of measurement (500–4000 cm^{-1}) $\tilde{\varepsilon}_{\infty\parallel}$ is real with a constant value of 5.78, although theoretical calculations [15] predicted a free-carrier absorption, corresponding to a plasma frequency of ~0.1 eV. On the contrary, $\tilde{\varepsilon}_{\infty\perp}$ is really complex due

to both interband and intraband electronic transitions, which produce a positive divergence in ε_2 at low frequencies. The values of the real and imaginary parts of $\tilde{\varepsilon}_{\infty\perp}$ have been obtained from Table I as $\varepsilon_{1\perp} = n_\perp^2 - k_\perp^2$ and $\varepsilon_{2\perp} = 2n_\perp k_\perp$, respectively. The other oscillator parameters were as follows: for $\tilde{\varepsilon}_\parallel$, $\omega_T = 867.8\,\text{cm}^{-1}$, $\Gamma = 0.001\,\text{cm}^{-1}$, and $S = 0.004$; for $\tilde{\varepsilon}_\perp$, $\omega_T = 1587.0\,\text{cm}^{-1}$, $\Gamma = 0.003\,\text{cm}^{-1}$, and $S = 0.031$. The resulting calculated values of n_o, k_o, n_e, and k_e are reported in Table I.

Liquid Mercury (Hg)*

E. T. ARAKAWA and T. INAGAKI†
Oak Ridge National Laboratory
Oak Ridge, Tennessee

The optical constants of liquid Hg at room temperature in the near infrared to the near UV have been measured extensively [1–11] by spectroscopic ellipsometry. The measurements were made both on a free surface under vacuum or inert gases [1, 4–7, 9, 10] and on a surface in contact with solid [2, 6, 8, 10, 11] or liquid [3] dielectrics. Except for the results of [2], the values of n and k obtained from these measurements agree in general with one another. However, the scatter of the data is far larger than the stated accuracies of individual results, which are reported with three or four significant figures. A careful recent study [11] finds no systematic difference between data obtained on a free surface and on a surface in contact with dielectrics. The measurements at wavelengths below 0.25 μm are very limited, with only two reflectance measurements at normal incidence, one on a free surface under vacuum from 0.06–0.6 μm [12] and one on a surface in contact with MgF_2 from 0.15–2.5 μm [8].

The room-temperature values of n and k are tabulated in Table I and plotted in Fig. 1. The data above 0.31 μm are from those determined by Inagaki *et al.* [11] as the mean values from the various ellipsometric measurements [1, 3–11]. The data below 0.31 μm are from the Kramers–Kronig (K–K) analysis made [11] on the normal-incidence reflectance data taken by Wilson and Rice [12] combined with the reflectance values above 0.31 μm calculated from the ellipsometric data of n and k. We believe that the n and k values given in Table I are accurate to ±0.2% on an absolute scale.

As with other liquid metals, the n and k spectra from the infrared to the UV are nearly free-electron-like up to the plasma wavelength at 0.177 μm. However, in contrast with some other liquid metals, the n and k values are significantly higher in the visible region than those given by the simple Drude expressions. Two absorption features at 0.149 μm and 0.124 μm

were assigned to excitations from the spin-orbit split 5d band to the valence band [12]. In addition, a weak structure was noticed at 0.191 μm, for which the possibility of an exciton or a surface plasmon was suggested [8, 12].

Liquid Hg is one of the easiest metals on which an ideally smooth surface can be made in a reproducible manner. Surface contamination due to oxidation has also been believed to be less severe than for any other metal except for a few inert metals such as gold. On the other hand, many metals dissolve readily in liquid Hg, forming an amalgam. In most measurements, therefore, the sample was distilled under vacuum or under a reduced pressure [1, 3–7, 9, 10], and in some cases, directly into the sample dish [4, 9, 10]. Prior to distillation, the sample was washed in dilute solutions of KOH and/or H_2NO_3 and then in distilled water to remove oxides [3, 5].

For measurements on a free surface, surface oxidation was the major source of error in the measured values of n and k. Most measurements were made under vacuum without exposing the surface to the atmosphere [1, 4–7, 9, 10]. It was reported [1], however, that the values of the optical constants in air did not change appreciably for up to 30 minutes and the changes in 60 minutes were still only of the order of the probable error. Since oxide and impurities tend to float to the surface, the overflow method was used [1, 11] to obtain clean surfaces.

Measurements on a surface in contact with dielectrics [2, 3, 6, 8, 10, 11] were relatively free from surface contamination. These measurements were also free from vibration of the liquid surface. However, two possible sources of error arose with this method. The first was due to imperfect optical contact of liquid Hg with the dielectric prism or window, and the second was due to strain in the dielectric overlayer. Schulz [13] employed the Ag-precoat method to obtain good optical contact of liquid Hg with several solid dielectrics. The liquid dielectrics used by Smith and Stromberg [3] avoided the contact and strain problems encountered with solid dielectrics.

Hodgson [1] measured a free surface by ellipsometry for the first time in an extended region from 0.365–2.40 μm using the rotating-polarizer method. The results showed unambiguously that the optical constants of liquid Hg did not agree with those given by the simple Drude formula for a nearly-free-electron metal. Lelyuk *et al.* [2] measured a sample in contact with a glass prism in the region from 0.45–1.54 μm. Multiple-reflection ellipsometry was used, and the angle of incidence was varied so that linear polarization of the incident light was restored in the reflected beam. The values of n and k obtained were much higher than those from the other ellipsometric measurements. This was later interpreted by Smith [5] as arising from imperfect contact between liquid Hg and the glass prism, and was reproduced experimentally by Faber and Smith [6].

Smith and Stromberg [3] measured liquid Hg in contact with three

different liquid dielectrics—cyclohexane, benzene, and distilled water—at 0.5461 μm. They used the conventional null method. The liquid Hg sample was immersed directly into the liquid dielectrics after vacuum distillation without exposure to the atmosphere. No difference was found in the n and k values measured under the different immersion liquids beyond the experimental accuracy of four significant figures. They analyzed theoretically the effects of surface layers, misalignment, and window birefringence on the measured values of n and k, and evaluated the limit of accuracy of their measurements.

Smith [4] and Faber and Smith [6] measured two different surfaces, a free surface under vacuum and a surface in contact with a quartz prism, in the region from 0.4–0.7 μm. They used a variant of the null method using three polarizers, one of which rotated continuously. The n and k values obtained for the two different surfaces were in good agreement. The Ag-precoat method was employed to obtain good optical contact of liquid Hg with the quartz prism. They attempted to clean the free surface using argon glow discharge. This increased the n and k values slightly. They also measured the effects of surface contamination during several days' exposure to atmosphere.

Smith [5] measured free surfaces under vacuum and He atmosphere at 0.5461 μm. The null method was employed with a commercial ellipsometer. The surface was cleaned by moving a stainless-steel barrier along the surface. Along with the ellipsometric measurement, surface tension and contact potential were measured to ensure that the surface was free of contamination. Ellipsometric measurements were made on a free surface by Busch and Guggenheim [7] in the region from 0.47–2.32 μm and on a surface in contact with a quartz prism by Choyke *et al.* [8] at three wavelengths in the visible.

Comins [9] extended the measurement on a free surface in the infrared up to 6.3 μm. A variant of Beattie and Conn's method [14] was employed. The n and k values obtained were in good agreement with those given by the semiempirical formulas of Smith [15]. The formulas were derived to explain the deviations of the optical constants of liquid Hg from the simple Drude theory in terms of backscattering of the electrons. Crozier and Murphy [10] extended the measurements on a free surface down to 0.25 μm. The method of Beattie and Conn [14] was used with an ellipsometer whose entire optical assembly was enclosed in a vacuum chamber. They also measured surfaces in contact with a quartz and a glass prism. The values of n and k obtained for these surfaces were slightly higher than those obtained for a free surface. For the surfaces in contact with a quartz and a glass prism, n and k values were obtained from reflectances measured with p- and s-polarized light. The values obtained were in a good agreement with those from the ellipsometric data in the case of the quartz prism, but not in the case of the glass prism.

Inagaki *et al.* [11] measured a surface in contact with a quartz prism in the region from 0.335–2.0 μm using a method similar to the one used by Crozier and Murphy [10]. Good consistency was obtained between the n and k values obtained from the ellipsometric data and the reflectance data taken simultaneously on the same surface. The earlier ellipsometric values of n and k obtained using various contact media were analyzed and shown to be consistent with each other within the experimental accuracies. They were also shown to be internally consistent using a K–K analysis of the ellipsometric n and k data combined with reflectance data in the shorter-wavelength region.

Wilson and Rice [12] measured normal-incidence reflectance of a free surface under vacuum in an extended region from 0.06–0.6 μm. A K–K analysis was performed on these data to deduce n and k values. However, extrapolation of the reflectance data into the shorter-wavelength region was made to give agreement of the optical-constant values at 0.6 μm with those given by the simple Drude expressions. Choyke *et al.* [8] measured normal-incidence reflectance of a surface in contact with MgF_2 in the region from 0.15–2.5 μm. Values of n and k were derived from these data by a curve-fitting method [16] using classical oscillators. The results were subject to a large uncertainty.

The temperature dependences of the optical constants were measured by Hodgson [1] at three different temperatures—22°, 124° and 230 °C—in the region from 0.6–2.4 μm. Smith [5] measured n and k values at 0.5461 μm at a number of different temperatures between 23° and 115 °C. From these measurements he derived

$$n = [1.593 + 0.00036T] \pm 0.004$$

$$k = [4.771 - 0.00155T] \pm 0.031,$$

where T was in degrees Celsius.

A few values of the optical constants have been reported [13, 17] which differ significantly from those obtained by ellipsometry. Schulz [13] reported values of n and k that agreed quite well with those given by the simple Drude theory in the region from 0.4–0.87 μm. However, it has been shown by the K–K analysis [11] and sum-rule calculations [7] that those values of the optical constants were questionable. The values were derived from reflectance data measured on a surface in contact with a quartz prism with unpolarized light incident at 45° and phase-shift data measured by an interferometric method for normal-incidence reflection from a surface in contact with mica. Mueller [17] also reported optical constants in the region from 0.26–2.48 μm, which were in good agreement above 0.38 μm with the simple Drude theory. The values were derived from reflectance

data measured with *s*-polarized light on a surface in contact with sapphire at normal incidence and at 45°. It was shown [11] that the precision of these reflectance measurements was far too low to permit an accurate determination of the optical constants. In addition to these two reports [13, 17], a few measurements [18, 19] of normal-incidence reflectances have been reported, which deviate slightly from those given by the n and k values determined by ellipsometry [1, 3–11]. The deviations were less than 0.02 in the absolute reflectance values. Bloch and Rice [19] have taken this discrepancy to be real, and proposed a model of the surface-transition zone to reconcile the discrepancy. Several papers [10, 20–24] have been developed along this line. A recent measurement made in our laboratory [25] with laser beams and with an Xe lamp at several wavelengths show that the measured values of reflectance agree well with those calculated from the optical constants determined by ellipsometry [11].

Gruppo Nazionale di Struttura della Materia del CNR
Università di Pavia
Pavia, Italy

The optical properties of Pd have been studied under a variety of experimental conditions and by several techniques [1–28]. Unfortunately, many results disagree as to the actual magnitude of optical structures, although the structure energies agree in almost every case. This depends on sample preparation, accuracy of the optical measurements, and on the method by which the experimental data are analyzed.

Experimentally, Pd is difficult to study in bulk samples, since it is readily contaminated and does not electropolish easily [19]. Vacuum deposition is relatively easy, but aging effects have been shown to be significant [13]. Although Pd does not oxidize as rapidly in air as other transition metals, Pd films show a critical dependence on thickness and evaporation rate [15].

The room-temperature values of n and k tabulated here (Table I and Fig. 1) were obtained from the following works and references therein: Windt *et al.* [27] from 525–12.5 eV; Vehse *et al.* [13] from 12.5–6.0 eV; Johnson and Christy [15] from 6.0–0.6 eV; Weaver and Benbow and Weaver *et al.* [18, 29] from 0.6–0.1 eV. Although the optical response in the visible–UV region has been clarified by Johnson and Christy [15], experimental differences and doubts regarding higher energies and the IR region still remain to be resolved. We chose the results that were in major agreement and were reported to have comparable experimental accuracy.

Windt *et al.* [27] evaporated Pd of unknown purity with an electron-beam current of 100 mA, at a rate of 10–12 Å/s onto polished silicon (111) wafers. The pressure in the deposition system was $\sim 5 \times 10^{-6}$ torr, and the substrate temperature was 80 °C. The film thickness chosen was 1000 Å, verified using a quartz-crystal monitor during deposition. Surface roughness was 18±3 Å, measured with an optical profilometer. The Auger-electron-spectroscopy profile indicated that oxidation was confined to the film surface. Absolute-reflectance (R) measurements were performed at thirty-six wavelengths (λ) from 24 Å to 1216 Å, using a

computer-controlled reflectometer at several incidence angles (usually sixteen angles between 10° and 85°). The incident-beam polarization was measured for $\lambda > 200$ Å using a rhodium-mirror polarization analyzer; for $\lambda \leqslant 200$ Å, the beam was assumed to be unpolarized. Although higher in overall magnitude, the shape of normal-incidence R agreed with the curve of Vehse *et al.* [13], showing the characteristic peak near 600 Å and the minimum near 700 Å. Using a nonlinear, least-squares, curve-fitting technique based on the χ^2 test, the values of n and k with their probable errors were determined from R versus incidence angle. The fitting procedure accounted for the effects of beam polarization, film thickness, and surface roughness in the calculation of the model reflectance [30]. The soft X-ray data of Henke *et al.* [22], the data of Vehse *et al.* [13], and the absorptivity of Weaver and Olson [20] are in moderate agreement with Windt *et al.* [27] optical constants in the range of overlap.

In Vehse *et al.* [13], Pd films were obtained by evaporation of Pd wire of 99.9995% purity in a vacuum of 10^{-8} torr. The deposition rate was ~150 Å/s, and the film thickness, measured by multiple-beam interferometry, ranged from 1600–2200 Å. The near-normal-incidence R was measured from 2–24 eV; in addition, R was measured as a function of the angle of incidence for a few selected photon energies. Even though the measurements were made *in situ*, R data were found to vary somewhat from sample to sample and to deteriorate with time; the data presented concern films with the highest R measured immediately after deposition. The prevalent conditions during evaporation and the history of the sample after its preparation must account for some discrepancies in the R values extending into the VUV [1–3, 7, 11]; such discrepancies occurred for all the opaque films evaporated on smooth substrates. Some scatter among data exists even for samples prepared *in situ* [11], mainly from 4 eV up to the region of the surface-plasma resonance at 7.3 eV. This probably results from surface-quality differences: the highest R values of Vehse *et al.* could indicate a better surface than in Ref. [27], even though their R is lower in the 10–24 eV range. In the low-energy range (4–6.5 eV) where experimental spectra overlap, R agrees well with that calculated from n and k measured on thin semitransparent films by Johnson and Christy [15] (see below). For multiangle measurements at selected energies, n and k were determined by a least-squares fit to Fresnel's equations. n and k were determined by the Kramers–Kronig analysis of the normal-incidence R spectrum from 2–24 eV. In the K–K integrals, the contribution $\Delta\theta$ to the phase change θ from the region above 24 eV was determined by interpolating the known values of $\Delta\theta$ at the selected energies mentioned above with a smoothly varying function. The results from the two methods agree within experimental error (±5%). Despite the good agreement of R values, n and k do not agree well with Johnson and Christy's values [15] in the 4–6.5 eV range, probably due to K–K interpolations.

Johnson and Christy [15] deposited Pd onto fused-quartz substrates at room temperature by vacuum evaporation of high-purity (99.97%) material. The evaporation was performed at pressure below 3×10^{-6} torr and at a fast rate (50 Å/s) to ensure the surface smoothness of the films. Several additional films were formed by sublimation at a rate of 0.3 Å/s. The reflectance was much higher for the quickly evaporated rather than for the sublimated films, so the optical constants determined from the former type were preferred. Moreover, annealing of the films in a nitrogen atmosphere indicated that quickly evaporated films were smooth and homogeneous, since they did not change after annealing like noble metals, whereas sublimated films changed. n and k as well as thickness d of the films were determined at eight selected wavelengths by inverting normal-incidence R and T functions simultaneously with the T function for p-polarized light incident at 60°. A three-parameter fit was used, and the resulting eight values of d (which presented a scatter of ±4 Å) were averaged. Then n and k were determined throughout the entire 0.5–6.5 eV spectral range using only normal-incidence R and T. The accuracy of the spectrophotometer in R (or T) was ±0.005, ±0.001 and ±0.0005, for the ranges $R>0.2$, $0.1 \leqslant R \ll 0.2$, and $R<0.1$, respectively. R spectra are in very good agreement (±0.01 in R) with those derived by Weaver and Benbow [18] (see below) from optical absorptivity between 0.15 and 4.4 eV. The optical constants exhibited a thickness dependence when the films were excessively thin (~100 Å). This behavior is qualitatively predicted by the Maxwell–Garnett theory [31]. n and k values listed are the averages of experiments on 277 and 375 Å films, which yielded results in agreement within the estimated error (less than ±1.5% in R and ±4% in n). As stated above, R processing (K–K transform) is exclusively responsible for moderate agreement of n and k values with those of Ref. [13]. R measured by Yu and Spicer [11] on opaque films from 2.2–11.6 eV was lower, because their slowly evaporated films were probably similar in structure to slowly sublimed films. This, with additional error introduced by K–K analysis, can account for most of the differences in their n and k values.

Weaver and Benbow [18] Pd samples were cut from a high-purity rod, mechanically polished to obtain a specular surface, then etched in boiling aqua regia. They were then annealed at 800 °C in vacuum (10^{-8} torr), followed by a high-temperature anneal under a partial pressure of He (1020 °C at 10^{-3} torr) to promote grain growth. Microscopic examination showed large grain (~4 mm) and an excellent work-free surface. Immediately prior to measurement, the sample was flashed in high vacuum to thermal-desorb any surface contamination. The absorptivity $A = 1 - R$ was measured at 4.2 K between 0.15 and 4.4 eV by a calorimetric technique. A K–K analysis was used to determine the optical constants [29]. For the extrapolations, a Drude form was used below 0.15 eV, and the data of Johnson and Christy [15], Vehse *et al.* [13] and Robin [7] were used from

4–50 eV. A power-law approximation $R(E) = R_o E^{-\beta}$ was used above 50 eV, with β adjusted to fit the independently determined dielectric function of Johnson and Christy [15], whose reflectance was in very good agreement in the overlap range. Although the optical spectra of Duisebaeva *et al.* [14] also present a structure near 0.46 eV, it is approximately three times stronger than that in [18]; moreover, another structure reported in [14] between 1.5 and 3 eV was not observed in [15] and [18]. Lafait *et al.* [21] also determined the infrared optical constants of Pd, from 0.1–0.5 eV, by means of surface-plasmon excitation. Unfortunately, their data were in disagreement with those of Refs. [14] and [18]. Furthermore, their conventional measurements of near-normal R and T from 0.5–6 eV also disagreed with those of Refs. [15] and [18], corresponding to a systematically lower reflectance.

Very recently, Fuzi *et al.* [32] used a prism-coupling (ATR) technique to measure the surface-plasmon properties of electron-beam-evaporated Pd on a glass slide. The ATR data as a function of angle of incidence at the He/Ne laser wavelength of 3.391 μm gave average values of $\varepsilon_R = 82.6$ and $\varepsilon_I = 109.3$ for several different prism-air space thicknesses. This gives $n = 5.21$ and $k = 10.48$, compared with values interpolated from Table I of $n = 4.08$ and $k = 14.05$. Fuzi *et al.* discuss variations of ε_R and ε_I for different kinds of metallic thin-film samples.

Vanadium (V)

G. GUIZZETTI and A. PIAGGI
Dipartimento di Fisica "A. Volta"
and
Gruppo Nazionale di Struttura della Materia del CNR
Università di Pavia
Pavia, Italy

There have been many measurements of the optical properties of V [1–23]. Although in the 1960s they were generally obtained on bulk samples mechanically polished, in later years films were preferentially used. The optical properties of the V films are strongly dependent on the preparation technique and the physical-chemical conditions (in particular, deposition rate and substrate temperature). To some degree this can explain scatter among the data. Moreover, V is particularly sensitive to oxide, but no author has quantitatively estimated the oxide-coating effect on the optical response. In any case, the best films give a response very similar to the bulk.

The room-temperature values of n and k tabulated here (Table I and Fig. 1) were obtained from the following works and references therein: Sonntag *et al.* [7] from 300–120 eV, Wehenkel and Gauthé [13] from 120–40 eV; Seignac and Robin [8] from 40–6 eV; Nestell and Christy [19] from 6–0.5 eV; Weaver *et al.* [12] from 0.5–0.1 eV. As a general rule we preferred data that were obtained "directly," for example, from R and T by inverting the Fresnel relations or from ellipsometry, which do not rely on extrapolations outside the measured spectrum. However, we also considered values derived from Kramers–Kronig analysis of reflectance [12] or electron-energy-loss spectra [13], based on a very wide energy range and accurate measurements: This ensured reliable results, which were in good agreement with the others in the overlapping regions. We have disregarded data that were insufficient and ambiguous, in terms of either the sample preparation and characterization or the measurement accuracy, especially when inexplicable or in clear disagreement with other researchers. This is particularly true in the IR region, where despite numerous ellipsometric measurements, we preferred the results of calorimetry [12], although limited to 0.1 eV.

In Table I we have retained three significant figures, but it is probably too generous for optical constants obtained from photometric or ellipsometric techniques.

Sonntag *et al.* [7] evaporated films onto substrates of zapon and aluminum using an electron gun. The optical absorption coefficient α was determined with an absolute accuracy of $\pm 20\%$, but the relative accuracy of adjacent regions was much better, about $1 \times 10^4\,\mathrm{cm}^{-1}$. The wavelength resolution in the continuous spectrum between 40 eV and ~300 eV of synchrotron light (of DESY accelerator) was better than 1 Å (0.1 eV at 40 eV, 8 eV at 300 eV). The α spectrum only showed an appreciable rise at 47.7 eV, while the strong oscillations reported by previous investigators [24, 25] appear to have been spurious. Above 200 eV, α quasi-linearly decreases to the value of $0.9 \times 10^5\,\mathrm{cm}^{-1}$ at 300 eV. The absolute magnitude of α was checked by performing oscillator sums to produce the expected value of $N_{\mathrm{eff}} \approx 8$ electrons.

Wehenkel and Gauthé [13] deposited V films by clean-vacuum (10^{-8}–10^{-7} torr) evaporation from bulk material on freshly cleaved rocksalt and floated off on distilled water. Film thicknesses from 200–400 Å were determined with an accuracy of about $\pm 10\%$, by weighing the substrate before and after evaporation. Electron-energy-loss spectra were obtained by transmission of 35 keV electrons in the 2–120 eV range with an accuracy better or equal to ± 0.5 eV and constant through the whole spectral range. To achieve statistical accuracy, a large number of spectra were recorded, using different specimens of different thicknesses. Through Ritchie's formula [26], the single-scattering volume losses were separated from the surface losses. Then ε_1, ε_2, and thickness were calculated by means of Kramers–Kronig relations. The energy-loss function was extrapolated by setting $\mathrm{Im}(-1/\tilde{\varepsilon}) = 0$ at $E = 0$ and assuming that it varies as $E^{-2.5}$ at high energies. In the superposition region (40–120 eV), the α spectrum derived is in good accord with that directly measured by Sontagg *et al.* [7]. In particular the peak at 47.7 eV differs only 3% in the energy position, although it is ~30% higher. So we report Kramers–Kronig-derived n values in the range 40–120 eV.

Seignac and Robin [8] evaporated V buttons of high purity (99.98%) with an electron gun onto mica and pyrex substrates, heated to a temperature between 350 and 400 °C. The films, grown at a rate of ≈5 Å/s, had thicknesses of 900–1400 Å. The optical constants were determined by both R measurements at two angles of incidence in the 4–50 eV range, and by Kramers–Kronig transforms; as far as the structure positions are concerned, the results were equivalent. The optical spectra in [8] are comparable with those of Ref. [7, 12, 19] in the respective superposition ranges; in particular, R is lower than in Ref. [19], and the α spectrum at high energy is flatter than in [7].

Nestell and Christy [19] evaporated polycrystalline thin films in a

vacuum system (the pressure was in the range $2–5 \times 10^{-7}$ torr) onto fused-quartz substrates heated to high temperature (550–700 °C). The evaporation rates were 200–800 Å/s for opaque films, and 20 Å/s for thin films of ~200 Å. X-ray analysis showed that the films were well crystallized with a lattice constant approximately 1% smaller than bulk value (due to uniform strain) and a grain size of 150 Å. Transmittance and absolute reflectance measurements were made in the 0.5–6.5 eV range with a double-beam spectrophotometer. The accuracy was about ± 0.005 in R. The reflectance of opaque films showed a strong evaporation-rate dependence; high rates avoid surface roughness, producing the most highly reflecting films (for example, at 6 eV, R increased ~6% when the evaporation rate was increased from 21 to 317 Å/s). The reflectance of rapidly evaporated opaque films was in quite good agreement with bulk-sample results [12], but it was much higher above 5 eV and lower below 1 eV. In the UV this discrepancy is attributed to surface roughness of the bulk samples, resulting from etching; in the IR it may be due to the different measurement technique used (calorimetry; see in the following). The optical constants n and k as well as the film thickness were determined by inverting the normal-incidence R and T along with the p-polarized T at a 60° angle of incidence, with R measured from opaque films. The estimate of instrumental error was ~1% in k and ~2% in n over most of the spectral range. The aforesaid differences in R between [19] and [8, 12] involve discontinuities in n and k at 0.5 eV and 6 eV, respectively.

In Weaver *et al.* [12], samples of V were spark-cut from electron-beam-melted buttons of high-purity material; then they were successively macroetched, mechanically polished, carefully electropolished, and finally very slightly polished with 0.3 μm diameter Al_2O_3. An X-ray Laue-gram indicated an unstrained surface. Although the samples were not single crystals, most or all of the illuminated surface was a single crystallite. A calorimetric method was used between 0.1 and 4.88 eV to determine the absorptivity $A = 1 - R$ at 4.2 K and a 15° angle of incidence. Room-temperature R measurements were made at 10°, 45°, and 60° for s- and p-polarized synchrotron radiation from 3.1–35 eV. A comparison of low-energy absorptivities with those calculated from the n and k values of Bolotin *et al.* [1] show good qualitative agreement, although A values are considerably lower in magnitude (that is, R was higher). Instead, above 5–6 eV R was lower than that of Seignac and Robin [8], probably due to an oxide layer. Optical constants were determined by Kramers–Kronig analysis: at low energy a Drudelike behavior was introduced; at high-energy, Sonntag *et al.* [10] absorption measurements were used to 300 eV; the range was extended up to 1000 eV (where $R = 1.4 \times 10^{-8}$) assuming $R(E) = R_o E^{-\beta}$ (with $\beta = 4.1$, from fitting R at 190 and 300 eV). The very wide energy range used in Kramers–Kronig analysis and the quite good agreement below 5 eV with the data of Nestell and Christy [19] make the n and k

values here reported in the 0.1–0.5 eV range more reliable than those obtained by ellipsometry [1–6, 22].

Although AlAs is one end of the important superlattice material $Al_xGa_{1-x}As$, it has not been investigated nearly as much because of its hydroscopic nature. This has necessitated some care in experiment often with a thin capping of GaAs, especially for superlattice structures containing alternate layers of AlAs and GaAs. Such a multilayer sample is more complicated to analyze if one wishes to extract n and k from spectroscopic ellipsometry or reflection–transmission experiments. The data chosen for this critique are listed in Table I and plotted in Fig. 1. Because there are several sources of data in a given energy range, we have chosen to list these separately rather than interspersing the data. Thus, in Table I the eV scale does not run consecutively but sometimes backs up to introduce new data with a bracket reference. This is usually indicated with a space.

At high energy we have used values of n and k obtained from a Henke-model calculation [1, 2] in the range 10,000–51.57 eV (1.240–240.4 Å). The atomic absorption edges are found at $K(\mathrm{Al}) = 1559.8$ eV, $K(\mathrm{As}) = 11{,}865$ eV, $L_1(\mathrm{Al}) = 87.01$ eV, $L_1(\mathrm{As}) = 1529.3$ eV, $L_{2,3}(\mathrm{Al}) = 72.78$ eV, $L_2(\mathrm{As}) = 1358.7$ eV, $L_3(\mathrm{As}) = 1323.5$ eV.

A gap appears to exist in experimental reflectivity data between 51 and ~6 eV, so no n and k data are available.

The region 5.6–1.7 eV has been studied with spectroscopic ellipsometry by Garriga *et al.* [3]. The AlAs sample was 1 μm thick, grown on a GaAs

(100) substrate; it was capped with a 17 Å GaAs layer. A multilayer model was used to extract the optical constants. A 6 Å oxide layer was assumed on top of the GaAs capping layer. We have read an expanded graph of ε_1 and ε_2 and calculated n and k using the equations

$$2n^2 = \varepsilon_1 + \sqrt{\varepsilon_1^2 + \varepsilon_2^2}$$

$$2k^2 = -\varepsilon_1 + \sqrt{\varepsilon_1^2 + \varepsilon_2^2}.$$

We carry three figures, but the data are surely not that good. The direct gap at 3.0 eV was defined in a fit of the absorption coefficient α versus eV, assuming a lineshape of a broadened two-dimensional interband minimum. These data are significantly different from data of Yim [4], who measured the transmission of bulk platelets of AlAs and determined both the indirect gap at 2.14 and the direct gap at 3.14 eV; this latter value is significantly different from that of Garriga *et al.*, and the k values are over an order of magnitude different; $k = 6.38 \times 10^{-2}$ at 3.0 eV [3] and $k = 1.79 \times 10^{-3}$ at 3.0 eV [4]. We have not found other measurements of k at the direct gap for comparison. To interpret the systematic variation of photoluminescence peak energies of GaAs/AlAs short-period superlattices, Nakayama *et al.* [5] cited values of 2.223 eV for the indirect gap and 3.125 eV for the direct gap of AlAs at 77 K.

An example of accuracy in reading two different graphs in the same paper is given for the values of k at 3.0 eV [3]: 5.3×10^{-2} from a graph of ε_1, ε_2 and 6.38×10^{-2} from a graph of α. This represents a 20% variation.

The 300 K values of index of refraction for energies below the direct gap has been measured by Fern and Onton [6] using the minimum-deviation method and a wedge-shaped sample (20°) of multigrained material. The experimental data were fit with the equation

$$\varepsilon = \varepsilon_r - i\varepsilon_i = \varepsilon_x + \frac{S_1 E_1^2}{E_1^2 - E^2 + iE\gamma_1} + \frac{S_2 E_2^2}{E_2^2 - E^2 + iE\gamma_2},$$

where ε_x represents the contribution to the dielectric constant by higher energy processes above the E_1 and E_2 interband transitions, and S_i and γ_i are the oscillator strength and damping constant of the E_1 and E_2 "oscillators." Finally, n is determined from $n = \mathrm{Re}[\varepsilon^{1/2}]$. This approximation is possible because in the spectral range of the measurements (<2.218 eV) the contribution from ε_i is very small. The fitting process reproduced the experimental data for n to ± 0.008 by using $E_1 = 3.9$ eV, $E_2 = 4.54$ eV, $S_1 = 3.019$, $S_2 = 3.030$, $\gamma_1 = 0.503$ eV, $\gamma_2 = 2.101$ eV, and $\varepsilon_x = 2.114$.

Monemar [7] used interference fringes to obtain 300 K values of n below the band gap for bulk samples. However, these values are considerably smaller (about -0.06) than those of Fern and Onton. A model of Adachi [8] for the system $Al_xGa_{1-x}As$ gives values of n much closer to Fern and Onton (presumably because the adjustable constants were chosen to fit these data) as does an extrapolation of the values for $Al_xGa_{1-x}As$ by Aspnes *et al.* [9]; for example, at 1.5 eV $n=2.995$ [6], 2.936 [7], 3.01 [8], and ~3.01 [9]. We elect to stress the experimental data of Fern and Onton but also show the calculated data [8] over a somewhat wider spectral range. Lorenz [10] measured $n=3.3$ at 2.2 eV, this number being about $+0.1$ larger than that of Fern and Onton at 2.2 eV. Such variations are probably due to the quality of the various samples.

In the lattice-vibration region, the reststrahlen spectrum has been measured by Rheinlander and Neumann [11] for bulk thin plates, but no optical constants were obtained by fitting an oscillator model to the data. The data of Minden [12] do not appear to be consistent with the results of Ref. [11], which we must attribute to the quality of the epilayers used in Ref. [12]. Minden measured R and T in the 1300–1400 cm^{-1} region for an epitaxial layer of AlAs grown on a GaAs substrate. The sample oxidized rapidly when brought out into the laboratory, and the data, which took several hours to obtain, surely contained effects of this layer. Although we expect an oxidation layer to be thin and transparent and not to perturb the results in the long-wave infrared, it is not clear what sort of material the hydroscopic nature of AlAs will produce on the surface.

Perkowitz *et al.* and Sudharsanan *et al.* [13, 14] have measured a heterostructure consisting of several layers of GaAs and AlAs. The substrate was 350 μm of undoped GaAs; on this were a 1 μm epitaxial layer of GaAs, a 0.2 μm layer of undoped AlAs, a 1 μm layer of Si-doped AlAs (the sample) and a capping layer of 250 Å of undoped GaAs. Measurements of reflectivity were performed from 200–450 cm^{-1} with reststrahlen peaks of AlAs and GaAs appearing along with interference fringes. Although the fit with a multilayer model was qualitatively good, the magnitudes were not matched very well except at the reststrahlen peaks. The parameters for GaAs were assumed to be known. The parameters for AlAs for a Lorentz-oscillator model of the form

$$\varepsilon = \varepsilon_\infty + \frac{S\nu_T^2}{\nu_T^2 - \nu^2 - i\nu\gamma}$$

were determined to be $\nu_T = 361.8\ cm^{-1}$, $S = 1.9$, $\gamma = 8.0\ cm^{-1}$, $\varepsilon_\infty = 8.2$. At low frequency, the dc dielectric constant is $\varepsilon_o = 10.1$.

Interestingly, the Raman spectrum yields most of the parameters needed

to calculate the IR spectrum. From Raman data, Onton [15] determined $\nu_T = 361.8\,\text{cm}^{-1}$, $S = 1.90$, and $\gamma = 0.97\,\text{cm}^{-1}$, and chose $\varepsilon_\infty = 7.8$. These can be used in the above formula to determine n and k also. The only drastic difference in the two sets of parameters is in the values of γ; the line width $0.97\,\text{cm}^{-1}$ seems too small [15], while the line width $8.0\,\text{cm}^{-1}$ seems too large [13, 14] for typical semiconductors. We calculated the reflectivity with both sets and found that the parameters of Perkowitz *et al.* give a better fit to the reflectivity in Ref. [11], agreeing with the experimental R within a few reflectivity percentage units almost everywhere; this assumes an uncertainty of a few cm^{-1} in the wave number axis as well. We did not attempt to refit the R data to obtain independent values of n and k, however. Therefore, we have listed these values [13, 14] in Table I.

Experimental transmission data for the two-phonon spectrum above ν_T were not found.

ACKNOWLEDGMENTS

We thank W. R. Hunter for providing the n and k values calculated from the Henke model.

Aluminum Antimonide (AlSb)

DAVID F. EDWARDS and RICHARD H. WHITE
University of California
Lawrence Livermore National Laboratory
Livermore, California

The refractive index, n, and the extinction coefficient, k, of AlSb have been measured for a limited number of samples. The two main reasons for this are that large high-quality single crystals are difficult to grow, and the surface of AlSb reacts rapidly with the atmosphere to produce a relatively thick contaminated layer.

One method for measuring the optical properties (n and k) of semiconductors, especially for the UV and visible regions, is spectroscopic ellipsometry. However, as pointed out by Aspnes and Studna [1] and Zollner *et al.* [2], contamination-free surfaces are needed for precise ellipsometric measurements. Using the wet-chemical etching procedures of Ref. [1], Zollner *et al.* have obtained AlSb surfaces of sufficient quality for ellipsometric measurements at room temperature from 5.8–1.4 eV. They report n and k values calculated from the measured pseudo-dielectric function. This is called the pseudo-dielectric function because no corrections were made for any surface overlayers that may be present. For surfaces free of these overlayers or by making the appropriate corrections, the ellipsometric measurements would give the "true" dielectric function. In either case, the n and k values for the near UV and visible regions are calculated from the ellipsometric measurements.

Strossner *et al.* [3] have measured the dependence of the energy gap absorptance of AlSb at room temperature for hydrostatic pressures from atmospheric up to the phase change at about 8 GPa. We have extracted the extinction coefficient from the atmospheric-pressure absorption coefficient for the energy range 2.2–1.4 eV.

Oswald and Schade [4] were among the first to report n and k value for AlSb in the infrared region. They simultaneously measured the transmittance and reflectance of a 1 Ω-cm p-type sample from about 1–15 μm. From these data they calculated n and k. They make no report of surface contamination effects and give only a plot of n and k. Their k values increase monotonically with wavelength indicating free-carrier absorption.

This, coupled with the small resistivity and possible surface contamination are reasons for excluding the Oswald–Schade data from the table that follows.

Turner and Reese [5] have measured the reflectance of room-temperature AlSb between 16 μm and 40 μm, which includes the infrared lattice reflectance band. By fitting their reflectance data to the classical dispersion theory [6], they calculated n and k values for the 20–38 μm spectral region. Their method is similar to that used by Spitzer, Kleinman, and Walsh [7] for SiC, and by Kleinman and Spitzer [8] for GaP. In the classical dispersion theory of solids [6], the susceptibility χ and conductivity σ in the neighborhood of a resonance frequency ν_o are given by

$$\chi = \rho \frac{1-\nu^2}{(1-\nu^2)^2+(\gamma\nu)^2} \tag{1}$$

and

$$\frac{\sigma}{\nu} = 2\pi\rho \frac{\gamma\nu}{(1-\nu^2)^2+(\gamma\nu)^2}, \tag{2}$$

where ν is the measured frequency divided by ν_o, σ is the conductivity divided by ν_o, and γ and ρ are dimensionless parameters. In the Lorentz theory, ρ is given by

$$\rho = \frac{Ne^2}{4\pi^2 m^* \nu_0^2}, \tag{3}$$

where N is the concentration of ion pairs, and m^* is their reduced mass. The dielectric constant is

$$\varepsilon = \varepsilon_0 + 4\pi\chi, \tag{4}$$

where ε_o is the high-frequency ($\nu >> 1$) dielectric constant. The four parameters (ε_o, ν_o, ρ, γ) were adjusted [5] for the best least-squares fit of the reflectance data to a single resonance. From these parameters the index of refraction and the extinction coefficient, n and k, are calculated from

$$n^2 = \tfrac{1}{2}[\varepsilon^2 + 4(\sigma/\nu)^2]^{1/2} + \varepsilon \tag{5}$$

and

$$k^2 = \tfrac{1}{2}[\varepsilon^2 + 4(\sigma/\nu)^2]^{12} - \varepsilon. \tag{6}$$

Turner and Reese [5] give the following values for their four parameters:

$$\nu_0 = (9.564 \pm 0.019) \times 10^{12}\ \text{sec}^{-1}$$

$$\rho = 0.1060 \pm 0.0005$$

$$\gamma = 0.0059 \pm 0.0005$$

$$\varepsilon_0 = 9.880 \pm 0.12.$$

Hass and Henvis [9] measured the fundamental reflection band of six III-V compound semiconductors at liquid helium-temperature. AlSb was one of the materials measured. They evaluated the oscillator parameters by comparing their measured reflectance with that calculated using the classical dispersion theory of Born and Huang [10]. The four parameters as found by Hass and Henvis are

$$\omega_0 = 318\ \text{cm}^{-1}$$

$$\varepsilon_\infty = 10.24$$

$$\varepsilon_0 - \varepsilon_\infty = 1.8$$

$$\gamma/\omega_0 = 0.02.$$

The n and k values are calculated using these parameters and the dispersion formulas of Ref. [10].

Pikhtin and Yas'kov [11] report a semiempirical method for calculating the dispersion of the refractive index using three adjustable parameters associated with the energy-band structure. For AlSb they use the data of Oswald and Schade [4] to evaluate the three adjustable parameters. Test calculations by one of us [12] and a comparison of their predictions to the data of Refs. [5] and [9] indicate that the indices are sensitively dependent on the values of the three parameters. It appears that indices over a spectral range broader than that of Ref. [4] are needed to improve the accuracy of the Pikhtin–Yas'kov calculated data for AlSb.

The indices of refraction and extinction coefficients for AlSb are given in

Table I and plotted in Fig. 1. Most of the data are for room temperature except those of Hass and Henvis [9], which are at liquid-helium temperature. The n and k values from 5.8 eV to 2.1 eV are the ellipsometrically measured data of Zollner *et al.* [2]. The k values for the absorption-edge region (2.2–1.4 eV) are calculated from the measured absorption coefficients of Strossner *et al.* [3]. The n values from 2.1 eV to 0.529 eV [0.5905 μm to 23 μm) were calculated from a Herzberger-type dispersion formula fit to the data of Refs. [2] and [5]. A total of 16 data points were used. As seen in Table I below, the index data in the 2.3–2.1 eV region has a slope discontinuity due to an interband critical point [2]. Data for energies greater than 2.1 eV were therefore not included in the dispersion-formula fit. The indices for wavelengths greater than 23 μm were also not included in the fit because of the onset of the infrared lattice band.

The Herzberger-type dispersion formula is [13]

$$n = A + BL + CL^2 + D\lambda^2 + E\lambda^4,$$

where $L = 1/(\lambda^2 - 2.8 \times 10^6)$ with the wavelength in angstroms. As explained by Herzberger and Salzberg [13], 2.8×10^6 is the square of the mean asymptote for the short-wavelength abrupt increase in the index for 14 materials (AlSb not included). For the 16 points from 0.5905 μm to 23 μm and at room temperature, the coefficients are

$$A = 3.204093$$

$$B = 1.874871 \times 10^7$$

$$C = 2.205306 \times 10^{14}$$

$$D = -4.144419 \times 10^{12}$$

$$E = -3.199325 \times 10^{-23}$$

The RMS error between the measured values and the dispersion-formula calculated indices is 0.179%.

For the reader's convenience, the same 16 indices were also fit to the modified Sellmeier-type dispersion formula [14]:

$$n^2 = 1 + A/(\lambda^2 - B) + C\lambda^2/(\lambda^2 - D),$$

where the wavelength λ is in angstroms. For the 16 data points, the coefficients are

$$A = 4.094753 \times 10^{-5}$$

$$B = -7.086745 \times 10^{-5}$$

$$C = 4.198623$$

$$D = 1.925813 \times 10^{-9}.$$

The RMS error is 0.371%.

The room-temperature n and k values of Table I from 25 μm to 100 μm were calculated from Eqs. 1–6 using the four parameters of Ref. [5]. These calculations were extended beyond the range of measurement to 100 μm in order to estimate ε_o ($=n^2$). The room-temperature measurements of Ref. [5] give $\varepsilon_o = 9.88$, compared with $n^2 = 11.36$ at 100 μm. At liquid-helium temperature (Ref. [9]) the parameter fit gives $\varepsilon_o = 12.04$, compared with $n^2 = 12.24$ at 100 μm.

Ghosh *et al.* [15] have developed a simple model for predicting the temperature and pressure coefficients of the refractive index of some zinc-blende semiconductors, AlSb included. They predict the temperature coefficient at constant pressure to be

$$\left(\frac{dn}{dT}\right)_p = 1.19 \times 10^{-4}\,\mathrm{K}^{-1}.$$

No wavelength or temperature range is given.

The pressure coefficient is predicted to be

$$-\left(\frac{dn}{dP}\right)_T = 34.10 \times 10^{-3}\,\mathrm{GPa}^{-1}.$$

No wavelength or pressure range is given. They have no measured data with which they can evaluate the accuracy of these predictions.

Aluminum Gallium Arsenide ($Al_xGa_{1-x}As$)

O. J. GLEMBOCKI
Naval Research Laboratory
Washington, D.C.
and
KENICHI TAKARABE
Department of Natural Science
Okayama University of Science
Okayama-City
Okayama 700, Japan

The $Al_xGa_{1-x}As$ system is technologically one of the most important alloy systems, especially when combined with GaAs. It forms the basis of quantum-well, superlattice, and single-barrier device structures, which in turn have a significant effect on high-speed electro-optics. Because of this, it would be of the utmost importance to have the optical constants, n and k, over a wide spectral range and over the concentration range of $x=0$ to $x=1$, in as narrowly spaced x intervals as possible, preferably $\Delta x=0.1$. This, however, is not the case. In fact, we could find only bits and pieces of data at almost random values of x over narrow spectral ranges, except for $x=0.3$.

There is, however, a fair amount of information about other physical parameters such as lattice constant, density, band gap, and phonon frequency. Because these parameters are useful in many applications, we list Adachi's values [1] for these most commonly used ones:

1. Lattice constant (Å) $a=5.6533+0.0078x$;
2. Density (gm/cm^3) $g=5.36-1.6x$;
3. Band gap (eV) $E_g=1.424+1.247x \quad (0<x<0.45)$
$=1.900+0.125x+0.143x^2 \quad (0.45<x<1.0)$;
4. LO phonon energy (meV) $\hbar\omega(\text{GaAs})=36.25-6.55x+1.79x^2$
$\hbar\omega(\text{AlAs})=44.63+8.78x-3.32x^2$;
5. TO phonon energy (meV) $\hbar\omega(\text{GaAs})=33.29-0.64x-1.16x^2$
$\hbar\omega(\text{AlAs})=44.63+0.55x-0.30x^2$.

We were able to find only one value of $x=0.3$ (within a typical

uncertainty of ±0.01) where UV, VIS, and IR data have been analyzed to give n and k. Otherwise, there are spectroscopic-ellipsometry data for n and k in the range of 6–1.5 eV for a number of x values near tenths [2], IR reststrahlen data for n and k from 1000–100 cm^{-1} for other values of x [3] and some measurements [4] and calculations [1, 5] of n from 2.5–0.5 eV. In Table I we display the values of x for which we found spectroscopic data in the various photon-energy ranges. It is clear that near $x = 0.3$, we have data for a wide wavelength range, but for other values of x, only data in the visible or IR are available.

In Table II we list n and k data for the values of x noted in Table I. In Fig. 1 we have plotted the values of the optical constants for $x = 0.3$. It is important to note that the end member GaAs ($x = 0$) was previously treated in *HOC I* [6], and that AlAs ($x = 1$) is discussed separately in this volume [7].

In the X-ray region from 10,000–51.5 eV (1.24–240 Å) there are no experimental data. The numbers for $x = 0.3$ listed in Table II were calculated using the Henke model [8, 9]. This model, based on calculated atomic scattering cross-sections, requires a knowledge of the density of $Al_{0.3}Ga_{0.7}As$, which is given by Adachi [1] to be $g(0.3) = 4.88$. The absorption edges of the atomic constituents are $K(Al) = 1559.88$ eV, $K(Ga) = 10368.2$ eV, $K(As) = 11865$ eV, $L_1(Al) = 87.01$ eV, $L_1(As) = 1529.3$ eV, $L_{2,3}(Al) = 72.78$ eV, $L_{2,3}(Ga) = 1145.0$, 1116.9 eV, $L_{2,3}(As) = 1358.7$, 1323.5 eV. The lower-lying energies may be perturbed by the bonding properties of the crystal material. It should be noted that this calculation can be used for any value of x provided that the parameters listed above are appropriately adjusted.

There appear to be no reflectivity data that would yield n and k in the ultraviolet down to 6 eV.

Aspnes *et al.* [2] measured n and k from 6–1.5 eV by spectroscopic ellipsometry from samples close to tenths in x. Values of x are usually determined by X-ray analysis to ±0.01. Care was taken to remove or account for the native oxide on the surface.

Interestingly, we find little data for the absorption coefficient at the band edge, presumably because the alloy samples are always on a GaAs substrate with a band gap smaller than the alloy film. This requires a reflection experiment or, for transmission, an etching process to remove the substrate but still support the film.

Below the fundamental band gap E_g, n has been measured for a number of x values [4]. Jensen [5] has developed a model to calculate n in the transparent region for ternary and quaternary semiconductors. Adachi [1] has used a different model to calculate n below the band gap. We have used both models for $x = 0.14$ to determine n and list the values in Table II. In the overlap region (1.2–1.5 eV) agreement is to ~1% at lower energies and increases to ~2% at higher energies. The Adachi calculation does not

seem to work well as E_g is neared, whereas the Jensen calculation is applicable much closer to E_g, even showing a plateauing of the n values. In addition, we have used the latter model [1] to calculate n below the respective band gaps for the tenth values of x, and we list them in Table II. It is also reported that the n values at 0.9 μm below all the band gaps vary linearly with x; $\Delta n = n(Al_xGa_{1-x}As) - n(GaAs) = 0.62x$ [10].

The n and k values in the far infrared for $Al_xGa_{1-x}As$ were obtained by fitting the reflectivity data [3] taken near normal incidence, that is, within approximately a 10° angle of incidence. The $Al_xGa_{1-x}As$ samples were grown by an isothermal liquid-phase-epitaxy (LPE) technique for x values ranging from 0 to 0.54. All materials had n-type carrier concentrations of less than $5 \times 10^{16}\,cm^{-3}$. The free-carrier plasma edge was not observed for $v > 50\,cm^{-1}$. The alloy compositions were evaluated by analysis of X-ray emission produced from the layer by the electron beam of an ARL model EMX-SM electron-probe microanalyzer. The accuracy of the composition measured was estimated to be within 2%; for example, $\Delta x = \pm 0.01$ for $x = 0.54$.

The optical phonons of the $Al_xGa_{1-x}As$ behave as the two-mode type [11–13]. The n and k values were calculated by the factorized form of the classical dispersion equation

$$(\nu) = (n + ik)^2 = \frac{(\nu_{11}^2 - \nu^2 - i\nu\gamma_{11})(\nu_{12}^2 - \nu^2 - i\nu\gamma_{12})}{(\nu_{t1}^2 - \nu^2 - i\nu\gamma_{t1})(\nu_{t2}^2 - \nu^2 - i\nu\gamma_{t2})}$$

where ν_{ti}, ν_{li}, γ_{ti}, and γ_{li} denote TO frequency, LO frequency, TO damping constant, and LO damping constant, respectively. The indexes $i = 1$ and $i = 2$ identify the parameters for the GaAs-like and the AlAs-like modes, respectively. Those values referred to are shown in Table III [10]. The n and k values are tabulated in the region of 5–100 μm in Table II.

ACKNOWLEDGMENTS

We thank W. R. Hunter for the calculation of n and k in the X-ray region with the Henke model.

Cadmium Selenide (CdSe)

H. PILLER
Louisiana State University
Baton Rouge, Louisiana

Cadmium selenide is a tetrahedral semiconductor with wurtzite structure in the hexagonal modification. CdSe is an optically uniaxial semiconductor with two components of the dielectric function. Measurements of the reflectivity spectra of CdSe crystals with polarized light have shown strong differences for the electric vector parallel ($\mathbf{E}\|c$) and perpendicular ($\mathbf{E}\perp c$) to the hexagonal axis. The room-temperature reflectivity of hexagonal CdSe was measured by Cardona and Harbeke [1] in the 0.8–12 eV region with linearly polarized light. Measurements were performed with the electric vector parallel and perpendicular to the c axis of the crystal. From these reflection measurements, extended with unpolarized light to the region between 11.3 and 22.5 eV, the optical constants were determined by means of the Kramers–Kronig technique. The crystals were polished in a crystal plane containing the hexagonal axis; however, no satisfactory etchant was found. The measurements were performed on polished, unetched surfaces; hence, the spectra obtained must be somewhat smeared out. The orientation of the c axis was determined by X-ray diffraction. The optical constants n and k, as read from the graph, are listed in Table I and plotted in Fig. 1 for both the ordinary (o) and extraordinary (e) rays. The numbers are probably correct to two figures.

Logothetidis *et al.* [2] investigated the real and imaginary parts of the ordinary and extraordinary dielectric functions of CdSe as a function of temperature with a scanning rotating-analyzer ellipsometer in the spectral range 1.3–5.5 eV. The measurements were made at 15, 210, 400, and 550 K. Automatic spectroscopic ellipsometry is an excellent technique to measure the real and imaginary parts of the dielectric function. On-line digitization of the data permits a fast and efficient analysis of the optical response of the semiconductor crystal. Ellipsometry is a sensitive technique used to investigate the optical response as it yields information on both the amplitude and the phase of the reflected polarized light beam. The data show strong structures in the optical spectra in the 4–5.5 eV region. For $\mathbf{E}\|c$ only one peak is seen, whereas three peaks are observed for $\mathbf{E}\perp c$. The absorption edge of CdSe exhibits three excitonic structures.

The lowest excitation energy is 1.741 eV at 295 K. These peaks have been interpreted in terms of interband transitions modified by excitonic interaction. The spectra of the dielectric function were obtained using the two-phase model (ambient and uniaxially anisotropic substrate) of the interface. No additional corrections for possible surface overlayers or roughness were made (for the edge excitons, three-phase models were used to take exciton-free layers into account). All measurements were made at an angle of incidence of 67.5°. The sample surface treatment included mechanical lapping and polishing with Syton (Monsanto Chemical Co.) in a plane surface parallel to the c axis. Chemical etching was used to remove the distorted layer produced by the mechanical polishing. The maximization of the real part of the complex dielectric constant, ε_1, around the E_1 structure (in the 4–5.5 eV region) was used as a criterion of quality of the surface. The method of surface preparation involved the cleaning of a surface growth with methanol and distilled water, while the sample was kept under the flow of dry nitrogen. This method gave the highest values of ε_1. No systematic investigation of the effect of a possible residual oxide layer was made. The values of $n_{o,e}$ and $k_{o,e}$ were calculated from the values of ε_1 and ε_2 as read from the graphs. The tabulated data are for 210 K (except the n_o and k_o values in the photon-energy range 1.3–2 eV, which were measured at 330 K). The numbers are listed in Table I and are plotted in Fig. 1 for both o and e rays.

The absorption spectra of undoped semi-insulating CdSe were measured from 0.6–1.8 eV by Rosen *et al.* [3]. The absorption spectra showed indirect absorption from energy levels of the shallow-acceptor defect, including a possible deep level at 1.3 eV. The absorption (of sample H_1) was fitted with the following expression for the absorption coefficient α:

$$\alpha(\hbar\omega) = A + B(\hbar\omega - E_0),$$

where $\hbar\omega$ is the photon energy, $T = 293$ K, $A = 2.5\,\mathrm{cm}^{-1}$, $B = 6.1 \times 10^{-3}\,\mathrm{meV}^{-2}\,\mathrm{cm}^{-1}$, and $E_0 = 110$ meV. E_0 is the threshold energy, A is the deep-state absorption near E_0, and B is an indirect absorption parameter. The slopes of the absorption components were nearly temperature-independent. The deep-level absorption changed with temperature, indicating association with the shallow acceptor. The undoped samples of CdSe were made semi-insulating by treatment with Se vapor. The thickness of the samples were in the 1.55–2 mm. The c axis of the samples was perpendicular to the surface. The absorption coefficient was calculated at each wavelength and corrected for reflection at the two surfaces. We calculated the imaginary part of the complex refractive index k from the absorption data given in the graph [3, Fig. 7]. The results are listed in Table I and are plotted in Fig. 1.

Beserman [4] measured the infrared absorption by pure CdSe platelets

in the range of frequencies $300\,cm^{-1}$–$465\,cm^{-1}$. The experiments were performed at room temperature with an experimental resolution of approximately $1\,cm^{-1}$. The observed main absorption peaks in the range of combination of optical modes are at 329, 354, 365, and $371\,cm^{-1}$. Raman-scattering measurements were made on the same platelets. The following phonon frequencies (cm^{-1}) were obtained from the infrared absorption and Raman data: $TA = 43.5$, $LO_\Gamma = 210$, $TO_\Gamma = 168$. Table I lists k as calculated from the data given in the graph in Beserman [4, Fig. 1]. Fig. 1 shows k.

The spectral dependence of the refractive index and birefringence of CdSe single crystals was investigated in a wide temperature and wavelength range by Lisita *et al.* [5]. The single crystals were grown by sublimation from the gaseous phase and had a conductivity in the range 10^{-10}–$10^{-11}\,\Omega^{-1}\,cm^{-1}$. The direction of the c axis was determined by using X-ray analysis with an accuracy of 20 min. In the spectral region between the fundamental absorption edge and $\nu = 5000\,cm^{-1}$, the refractive index was determined by the prism method. Prisms were cut in such a way that the optical axis of the crystal was parallel to the refracting edge. The absolute error in determining n was about 5×10^{-4}. In the spectral region $\nu < 5000\,cm^{-1}$, the interference method was used to determine the refractive index n_o of the ordinary beam. The corresponding values of n_e were calculated according to the equation $n_e = n_o + \Delta n$. The absolute error in determining n_o using the interference method was about 5×10^{-3}. The dispersion of the birefringence was measured by the method of interference of polarized beams. The absolute error in determining Δn was between 2×10^{-5} and 4×10^{-5}. The measurements were performed in a temperature interval between 100 and 600 K. The room-temperature measurements show that $n_e > n_o$ for all crystals. The numerical values of n_o and n_e are in good agreement with the data by Bond [6]. We have listed the values of n_o and n_e in Table I. Pikhtin and Yas'kov [7] have refitted the data with an oscillator-model formula obtained from the Kramers–Kronig dispersion relations. Additional data points listed in Table I and plotted in Fig. 1 were calculated using these analytic expressions [7].

Transmission and reflection spectra were measured on CdSe single crystals in the region of 3.6–5.9 eV at 109 K and at room temperature by Lange and Iliev [8]. The optical constants were calculated from these data and agree well with the data of Ludeke and Paul [9] on CdSe thin films and agree semiquantitatively with those obtained by ellipsometry [2]. The plate-shaped, single-crystal samples were grown from the vapor phase. Thickness of the samples was measured by means of an interference microscope and ranged between 100 and 150 nm. The in-out technique was used in the optical experiments. The multiple internal reflections in the sample were neglected in calculating the absorption coefficient and the refractive index from experimental spectra.

Polarized synchrotron radiation was used by Freeouf [10] to measure the reflectance spectra for photon energies between 0.6 and 30 eV at temperatures between 90 and 400 K. The optical constants were determined by Kramers–Kronig analysis. Synchrotron radiation provides an intense polarized continuum spectrum of light throughout the ultraviolet spectral region. The reflectance was measured by the rotating-light-pipe, scanning-reflectometer technique. The precision of the reflectance measurements was lower for photon energies larger than 8 eV. The single crystals of CdSe were cleaved just prior to mounting in the experimental system.

Terekhova *et al.* [11] measured the ordinary and extraordinary refractive index in the photon-energy region of 1.88–1.76 eV using two-beam interferometry at 5 K. The observed dispersion in the refractive indices was interpreted in terms of exciton states.

Beserman and Balkanski [12] measured the vibrational properties of CdSe at room temperature. The reflectivity was measured on a single crystal of CdSe containing 0.5% S, for $\mathbf{E} \perp \mathbf{c}$ and $\mathbf{E} \| \mathbf{c}$, in the frequency range 100–350 cm^{-1}. The resolution was 1 cm^{-1} in the entire range studied. The real and imaginary parts of the dielectric constant were deduced from the reflectance data by means of the Kramers–Kronig relations in the frequency range 100–300 cm^{-1}. The optical-mode frequencies were calculated from the following equations:

$$\omega_{TO} = \varepsilon_{i\,\max} = 2nk_{\max}$$

$$\omega_{\mathrm{LO}} = \mathrm{Im}(-1/\varepsilon)_{\max} = [2nk/(n^2+k^2)]_{\max}$$

For each polarization two types of oscillators were observed: the TO mode of pure CdSe, whose frequencies are; for $\mathbf{E} \| c$, $\omega_{\mathrm{TO}} = 166.5\ cm^{-1}$, and for $\mathbf{E} \perp c$, $\omega_{\mathrm{TO}} = 169\ cm^{-1}$; and the localized-mode frequencies of S in CdSe. In both polarizations, two localized modes were observed: for $\mathbf{E} \| \mathbf{c}$, 262 cm^{-1} and 266.5 cm^{-1}; for $\mathbf{E} \perp c$, 263 cm^{-1} and 269 cm^{-1}. The LO-mode frequencies were calculated either from $\varepsilon_r = 0$ (ε_r is the real part of the dielectric constant) or from $\mathrm{Im}(-1/\varepsilon) = \max$. Two sets of LO modes were observed: for pure CdSe, $\omega_{\mathrm{LO}} = 210\ cm^{-1}$ ($\mathbf{E} \| c$) and $\omega_{\mathrm{LO}} = 212\ cm^{-1}$ ($\mathbf{E} \perp c$); for *S* in CdSe, $\omega_{\mathrm{LO}} = 262.5\ cm^{-1}$, $268.5\ cm^{-1}$ ($\mathbf{E} \| c$), and $\omega_{\mathrm{LO}} = 263.5\ cm^{-1}$, $270.5\ cm^{-1}$ ($\mathbf{E} \perp c$). We calculated the real and imaginary parts of the complex refractive index from the corresponding real and imaginary parts of the dielectric constant for the ordinary and extraordinary rays from the experimental data given in the graphs [12, Figs. 2 and 3]. The results are listed in Table I and plotted in Fig. 1.

Geick, Perry, and Mitra [13] measured the reflectivity of single-crystal CdSe with linearly polarized light at room temperature and at liquid-nitrogen temperature. The reflectivity was measured in the spectral region

from 70 cm^{-1} to 375 cm^{-1}. Transmission measurements were made with unpolarized light on polycrystalline samples. The extinction coefficient k was determined from the experimental results for the spectral region from 80 cm^{-1} to 500 cm^{-1}. The spectra were analyzed by means of an optimum fit with a classical dispersion formula. The transmission measurements showed several multiphonon peaks, which were interpreted in terms of four representative phonon energies for the edge of the Brillouin zone.

Verleur and Barker [14] measured the infrared reflectivity over the frequency range from 100 cm^{-1} to 400 cm^{-1} at 15 and 300 K with polarized light. A resolution of 2.5 cm^{-1} was maintained over the entire frequency range. Agreement between different runs on the same specimen was within 1%. "Pure" CdSe was found to contain up to 2% S. A single-crystal specimen containing 1.5% sulphur was used in the reflectivity measurements. Classical oscillator fits of the reflectivity spectrum were used to determine the mode parameters and related constants.

Cadmium Sulphide (CdS)

L. WARD
Coventry Polytechnic
Coventry, England

Cadmium sulphide is a member of the II-VI group of semiconducting compounds formed by alloying one element from group II of the periodic table with another from group VI. The energy gap between the valence and conduction bands is about 2.4 eV and CdS has been used extensively in photoconducting cells, being effective in the ultraviolet and blue parts of the spectrum. In addition, there is a strong absorption band in the infrared due to lattice vibrations (phonons). At short wavelengths there are also absorption bands due to electron transitions involving inner energy levels. The normal crystal structure is hexagonal close-packed (wurtzite), which is in space group C6mc, and most of the reported values of the optical constants of CdS have been for this form of the compound. However, a face-centered cubic form of CdS can also be prepared (zinc-blende structure, space group $F\bar{4}3m$), and a few results for this material are also available. In dealing with hexagonal CdS, the optical properties of the single crystals depend on whether the electric vector of the incident radiation is vibrating perpendicular to or parallel to the c axis, that is, the axis at a right angle to the crystal hexagon. The main impurities occurring in CdS are iron, potassium, and sodium; it is possible to obtain material where all the impurities total less than 0.01%. Values of n and k for CdS are given in Table I and graphed in Fig. 1; the wavelength range covered is 6×10^{-4} to 1000 μm and, wherever possible, slight wavelength overlaps have been included between the different sets of results.

Hexagonal Cadmium Sulphide

Henke [1] has described a method of calculating optical constants at X-ray wavelengths (0.0006–0.0124 μm) from X-ray scattering data; the scattering coefficients f_1 and f_2 for all elements are given in detail by Henke *et al.* [2]. For CdS, the following relationships apply;

$$n = 1 - 4.45\lambda^2(f_{1\mathrm{Cd}} + f_{1\mathrm{S}})$$
$$k = 4.45\lambda^2(f_{2\mathrm{Cd}} + f_{2\mathrm{S}}),$$

where λ is the wavelength in μm.

The calculated values of n in this region, which are given in Table I, were generally just less than unity, whereas peaks in k were produced at 0.0075 μm ($L_{II,III}$ transition in S) and 0.0028 μm (M_V in Cd). Cardona and Haensel [3] made a direct measurement of the absorption coefficient, α, between 36 and 120 eV (0.01–0.34 μm) of evaporated thin films of CdS; k may then be calculated from the relationship, $k = \alpha\lambda/4\pi$, a peak being observed at 0.0225 μm (55 eV). Where overlap occurs, there is reasonably good agreement between the values of k from Henke and those of Cardona and Haensel.

Cardona and Harbeke [4] measured the reflectances R_p and R_s between 2 and 12 eV (0.1–0.62 μm) of platelets of CdS grown from the vapor phase, although they claimed that similar results could be obtained from etched solid material; they used a Kramers–Kronig (K–K) analysis to calculate n and k for the cases of both $\mathbf{E}_{\parallel c}$ and $\mathbf{E}_{\perp c}$. Peaks were observed in n at 0.490, 0.264, and 0.143 μm (both states of polarization) and at 0.234 μm ($\mathbf{E}_{\perp c}$) and 0.175 μm ($\mathbf{E}_{\parallel c}$); there were peaks in k at 0.490, 0.225, 0.155, and 0.136 μm (both) and at 0.200 μm ($\mathbf{E}_{\parallel c}$) and 0.253 μm ($\mathbf{E}_{\perp c}$); the peaks at 0.490 μm correspond to the main energy gap (2.53 eV). The authors were able to correlate all these peaks with different electron transitions within the energy-band structure of cadmium sulphide. Their values of n and k for both states of polarization are included in Table I. Balkanski and Petroff [5] determined ε_1 and ε_2 between 1 and 20 eV (0.06–1.24 μm) using measurements of reflectance from the natural faces of CdS crystals. They found a similar set of absorption peaks to those of Cardona and Harbeke with the addition of a further peak at 14.5 eV (0.0855 μm). Freeout [6] used synchrotron radiation to measure the reflectance of the natural faces of CdS crystals between 0.04 and 2.0 μm using a rotating-light-pipe scanning reflectometer originally devised by Gerhardt and Rubloff [7]. He presented graphs of ε_1 and ε_2 versus wavelength, finding a strong absorption doublet at 13.5 eV (0.092 μm), which is close to the M_1 transition in sulphur; he suggested that this doublet was produced by spin-orbit splitting of this transition.

In the region around 0.5 μm, which includes the main absorption band due to electron transitions between the valence and conduction bands, Brodin and his collaborators have made important contributions. Brodin and Strashnikova [8] determined n for single-crystal CdS films by an interference technique; for radiation polarized with the E vector perpendicular to the c axis, there was a single absorption peak at about 0.48 μm, whereas for the E vector parallel to the c axis, there were two close peaks centered about the same wavelength. In addition, there was also a wide absorption band near 0.28 μm, present in both states of polarization. Brodin *et al.* [9] also measured the reflectance of single-crystal material but at a temperature of 4.2 K; for E vibrations that were polarized parallel to the c axis, a single absorption maximum was found at 0.483 μm; for

polarization at right angles to the c axis, two maxima were discovered at 0.487 and 0.463 μm. Brodin [10] has published values of n versus wavelength between 0.5 and 0.65 μm for monocrystals of CdS at temperatures of 20 K and 290 K. He measured the reflectance and used K–K analysis to find n for **E** both parallel and perpendicular to the c axis; over the range of wavelengths studied, n_e ($\|$) was always about 2% larger than n_o ($\perp$).

Kreisel *et al.* [11] studied CdS in the range of 0.5–0.7 μm under different levels of light excitation and at low temperatures (5 K). At low excitation levels, excitons (see below) were observed, but at high levels of excitation, an electron-hole plasma was produced. n_o was larger than n_e up to 0.510 μm, but at the longer wavelengths this situation was reversed. When the CdS contained free-carrier impurities ($2 \times 10^{18}\,cm^{-3}$), the value of n at the absorption peak was reduced from 5.0 to 3.5. Lampicki [12] found three peaks in his reflectance curves at 0.4874, 0.4844, and 0.4731 μm, which he identified with electron transitions between the valence and conduction bands in the Γ direction in the Brillouin zone. All three peaks were present for $\mathbf{E}_{\perp c}$ but only the two at lower wavelengths for $\mathbf{E}_{\|c}$; these results are similar to those found by Brodin. Gobrecht and Bartschat [13] determined n and k by Denton's method [14], which required a knowledge of both the reflectance and transmittance and yielded values for both the *o*- and *e*-rays between 0.49 and 0.65 μm at both 20°C and −180°C. For the longer wavelengths, n_o was smaller than n_e, but there was a crossover at about 0.51 μm. They concluded that just beyond the absorption edge at 0.485 μm, CdS shows evidence of direct electron transitions between the valence and conduction bands. At higher photon energies, the form of the absorption curve was probably determined by the combined effects of indirect transitions and direct transitions between nonparabolic energy bands.

Bienewski and Czyzek [15] and also Czyzek *et al.* [16] have made measurements of n between 0.5 and 1.4 μm at 298 K using the minimum-deviation method reported by Czyzek *et al.* [17] in which the chopped radiation was detected by a thermocouple; tables of values for both the *o*- and *e*-rays ($\mathbf{E}_{\perp c}$ and $\mathbf{E}_{\|c}$) were produced in which n is quoted to three decimal places. These values are reproduced in Table I. Using a nonlinear regression technique, Sanchez-Gomez *et al.* [18] claimed to have refined these results of Bienewski and Czyzek for the dispersion of CdS and were also able to calculate the residuals for each wavelength. However, this process made little difference to the original values of n, causing only small alterations in the third decimal place. Another investigator in this part of the spectrum was Devore [19] who also used the prism technique and was able to produce Sellmeier-type equations for both the *e*- and *o*-rays. Reynolds *et al.* [20] have also published graphs of n and α against wavelength between 0.5 and 1.0 μm for single-crystal cadmium sulphide.

Francis and Carlson [21] have published a set of results for n measured

on polycrystalline cadmium sulphide between 1 and 14 μm determined by the minimum-deviation method involving a narrow-angled prism of the material. They did not distinguish between the *o*- and *e*-rays, but their values of n link well with those of Bienewski and Czyzek for *e*-rays; they have been quoted extensively in Table I.

Vitrikhovskii *et al.* [22], using single crystals of CdS, have investigated the variation of n with temperature over the range 100–600 K. The refractive index was measured between 0.5 and 1.6 μm by the prism technique and by an interference method; there was good agreement between their published values and those of Bienewski and Czyzek at 300 K. Both n_o and n_e increased with temperature, dn/dT being about 8×10^{-5}/°C.

Thin Films

Gottesmann and Ferguson [23] measured the reflectance of thin films of CdS between 0.4 and 0.75 μm finding an absorption edge at 0.52 μm. The most rapid deposition rate that they used (90 Å/min) produced the highest values of n, but these were still less than those for bulk material, presumably because of the low packing density of the film particles. Hall [24], who measured the reflectance and transmittance of thin films on quartz substrates between 0.2 and 0.6 μm at different deposition rates, observed peaks in n at 0.25 and 0.5 μm and in k at 0.23 μm. The absorption maximum occurred close to the s–p transition wavelength of sulphur at 0.229 μm. n was found to be proportional to the deposition rate up to 0.40 μm but not at the higher wavelengths, whereas k did not appear to be affected by the deposition rate. There was a region of anomalous dispersion between 0.40 and 0.50 μm due to the excitation of electrons from the valence to the conduction band; the absorption edge was measured at 0.51 μm.

De la Plaza *et al.* [25] studied RF sputtered films of CdS and published values of n versus wavelength over the narrow range 0.5–0.7 μm for different sputtering pressures. The largest values of n were obtained at the lowest deposition pressure, but again these were less than those for crystalline cadmium sulphide. Strashnikova *et al.* [26] using a prism of very small angle (0.75×10^{-4} rad), noted that n increased slightly with the thickness of the prism up to 4 μm thick at wavelengths between 0.46 and 0.49 μm. In another paper, Strashnikova *et al.* [27] studied the variation of the wavelength of the inversion point (where n is the same for both *o*- and *e*-rays) with film thickness. The inversion wavelength decreased from 0.510 μm for films thicker than 1.5 μm, to 0.498 μm at a thickness of 0.5 μm, the authors claiming that this effect was due to the decreasing oscillator strength of the exciton.

Khawaja and Tomlin [28] measured both the reflectance and transmittance of thin films deposited on quartz wedges with 3° angles to eliminate

reflection from the back of the substrate. The wavelength range covered was 0.3–2.0 μm and three substrate temperatures were used: 20, 140, and 180°C. The highest substrate temperature generated the largest values of n and k, presumably because the higher mobilities of the deposited particles produced a more densely packed film, but the values of n were still lower than those for bulk materials. Wohlegemutt *et al.* [29] also measured the normal-incidence reflectance and transmittance up to a wavelength of 1.0 μm for both polycrystalline and amorphous CdS films deposited on sapphire; they compared their results with those of Cardona and Harbeke [4], Khawaja and Tomlin [28] and Kuwabara [34], noting a peak in n at about 0.5 μm in all the sets of results. However, the curves of n versus wavelength produced by Wohlegemutt *et al.* were at all points lower than those by the other authors; on the other hand, the values of k were in much better agreement. n initially fell as the wavelength decreased over the anomalous-dispersion region, but commenced to increase again as the wavelength approached 0.3 μm. The results of Khawaja and Tomlin are regarded as being the best in this region of the spectrum, and they are given in Table I.

Shklyarevskii *et al.* [30] working between 0.45 and 0.65 μm used ellipsometry to measure the optical constants of a thin film of CdS deposited on a chromium substrate. n was found to be a function of both the film thickness and the wavelength, but all the curves showed a maximum at about 0.485 μm; k, however, was independent of thickness and increased with decreasing wavelength. Czyzek *et al.* [17] have reported studies on synthetic CdS from the visible region up to 1.4 μm. Over this limited wavelength range, the following Sellmeier-type equations were derived for n_o and n_e:

$$n_0^2 = 5.235 + 1.819 \times 10^7/(\lambda^2 - 1.651 \times 10^7)$$

$$n_e^2 = 5.239 + 2.076 \times 10^7/(\lambda^2 - 1.651 \times 10^7).$$

Measurements on polycrystalline films of CdS have been made by Soera and Serdyuk [31]. A complicated structure in the reflectance curve near the absorption edge was attributed to layers of excitons and possibly also to lattice defects. Nolly *et al.* [32] have carried out an ellipsometric study of spray-pyrolized thin films of CdS over the visible spectrum. Hall and Ferguson [33] determined the optical constants of films of CdS from measurements of reflectance and transmittance between 0.6 and 14 μm; n was found to be independent of the deposition rate and also decreased monotonically with wavelength from 2.52 at 0.6 μm to 2.26 at 14.0 μm, whereas k showed a linear increase with wavelength and was also dependent on the deposition rate up to 7 μm, being largest for the highest rates. Their values of n agree reasonably well with those of Bienewski and

Czyzek. As examples of the optical constants of thin films in this spectral region, Hall and Ferguson's results are reproduced in Table I.

Kuwabara [34] worked with polycrystalline evaporated films between 0.4 and 1.0 μm finding a maximum in n of 2.65 at 0.5 μm where k was equal to 0.18; the absorption edge, corresponding to electron transitions from the valence to the conduction band, occurred at the same wavelength. He claimed that the optical properties of the films were similar to those for a single crystal, but his values for n were significantly smaller than those of Khawaja and Tomlin for similar films. Elizelde and Rueda [35] measured the reflectance and transmittance of thin-film specimens and, using the exact equations for these parameters produced by Bauer [36] (which take account of both faces of the substrate), calculated the optical constants between 0.5 and 2.5 μm. Between 0.5 and 10.0 μm, Miloslavski [37], working with layers of single-crystal CdS of thickness 2–3 μm deposited on a sodium-chloride substrate, measured the transmittance, from which n could be calculated. He was interested in the effect on n of the presence of impurities and noted that as the proportion of impurities was increased up to 1.2×10^{18} carriers/cm^{-3}, the values of n between 5 and 18 μm decreased by about 2.5%.

Infrared region

In the spectral region from 10–50 μm several studies of the optical properties of cadmium sulphide have been made. Collins [38] has reported reflectance values for unpolarized radiation measured on a single crystal between 20 and 48 μm; these showed a minimum reflectance at 32 μm followed by a peak at 38 μm. Taking the value of the dielectric constant at very long wavelengths, e_0, as 9.3, the value of e_∞ as 5.76, and the transverse optical phonon as 241 cm^{-1} (41.5 μm), the wave number of the longitudinal optical phonon was deduced from a Lorentz-type equation to be 305 cm^{-1} (37.8 μm). Balkanski and Besson [39] measured the reflectance between 15 and 30 μm at both 293 K and 80 K and found that their results could be explained in terms of multiple-phonon processes, that is, two or three phonons being excited by the absorption of a single photon. Values of k over this wavelength range calculated from their absorption-coefficient graph are incorporated in Table I. Deutsch [40] also studied the infrared absorption of CdS between 10 and 25 μm, finding bands at 22.55 and 23.15 μm when the **E** vector of the incident radiation was parallel to the c axis of the crystal, and at 19.95 μm when the **E** vector was perpendicular to the c axis; he needed four phonons to explain his results. As the absorption curves were determined in more detail, extra phonons had to be invoked to explain all the peaks; for example, Marshall and Mitra [41] needed six phonons, and Balkanski *et al.* [42] required ten. Balkanski *et al.* also measured the absorption coefficient α of CdS between 27 and 120 μm and have presented a graph of α against wave number from which values of k

over this spectral region have been calculated and are presented in Table I. Because a logarithmic scale was used for α, it is difficult to take precise readings from this graph, and the estimated accuracy in k is no better than the second decimal place. In their experiment CdS was deposited on silicon whose (111) axis was at right angles to the surface; the layers were then found to have their c axes also at right angles to the substrate. For radiation vibrating parallel to the c axis, the transverse optical phonon, ν_t, was at 233.5 cm^{-1} (42.8 μm) and the longitudinal optical phonon, ν_l, was at 305 cm^{-1} (32.8 μm); radiation vibrating at right angles to the c axis gave a transverse optical phonon at 242 cm^{-1} with the longitudinal phonon being unchanged.

Balkanski [43] has given a graph of n versus wave number covering the range of wavelengths between 27 and 60 μm. Values of n read from this graph are incorporated in Table I.

Manabe *et al.* [44] measured the reflectance of polished specimens of CdS at wavelengths between 20 and 100 μm and at temperatures of 100 and 300 K; they calculated n and k using the following version of the Lorentz dispersion formulas:

$$n^2 - k^2 = \varepsilon_\infty + N(\nu_t^2 - \nu^2)/((\nu_t^2 - \nu^2)^2 + \gamma^2\nu^2)$$

$$2nk = N(\gamma\nu)/((\nu_t^2 - \nu^2)^2 + \gamma^2\nu^2).$$

For $\mathbf{E}_{\parallel c}$, they used $\varepsilon_\infty = 5.4$, $N = 1.92 \times 10^5$ cm^{-2}, $\nu_t = 234$ cm^{-1}, $\nu_l = 300$ cm^{-1} and $\gamma = 3.98$ cm^{-1}; for $\mathbf{E}_{\perp c}$ the constants were 5.3, 1.82×10^5 cm^{-2}, 241 cm^{-1}, 306 cm^{-1}, and 5.54 cm^{-1} at 300 K. Their values for n and k are those quoted in Table I to represent this part of the spectrum; from their published graphs, it is just possible to read off the values to the second decimal place.

Barker and Summers [45] have reported values for the dielectric constants both parallel and perpendicular to the c axis of platelets of single-crystal CdS measured by an interference method between 70 and 330 μm. Their results are given in Table I.

The refractive index of CdS between 100 and 1000 μm was determined by Hattori *et al.* [46] using a channel-spectrum technique in conjunction with a Michelson interferometer coupled to a germanium bolometer. The refractive index was calculated from the transmission interference maxima and minima. n for CdS appeared to be constant over this range of wavelengths: 3.27±3% for $\mathbf{E}_{\parallel c}$ and 3.11±2% for $\mathbf{E}_{\perp c}$. Both these values were up to 10% higher than those produced by other authors such as Berlincourt *et al.* [47], Verleur and Barker [48], and Barker and Summers [45] who have also made measurements in this spectral region.

Excitons

Gross *et al.* [49] investigated the presence of excitons, that is, electron-hole pairs having energy levels within the energy gap, at 4.2 K, finding 13 narrow emission lines between 4853.5 and 4889.5 Å near the main absorption edge. They also found a series of equally spaced lines between 5150 and 5600 Å, which were ascribed to electron transitions involving phonons. From their results, an absorption peak could be predicted in the infrared at 47 μm, compared with the now-accepted value of 42.25 μm. Pevtsov and his colleagues [50, 51] carried out thorough investigations on two types of excitons, specified as type A and type B, due to the double degeneracy of the valence band. Another group that studied excitons was Henneberger *et al.* [52], who used artificially grown platelets of CdS and measured the transmission between crossed polaroids. Voigt *et al.* [53] studied the energy spectra of type A and B excitons by reflectance and transmittance measurements on very thin but highly perfect crystals at 1.8 K. Exciton studies were also carried out by Lambe *et al.* [54] and by Thomas and Hopfield 55, 56, 57]. The properties of excitons in semiconductors has been well-covered in a review article by Thomas and Timofiev [58].

Cubic Cadmium Sulphide

Cubic cadmium sulphide was studied by Cardona [59], who measured the normal-incidence reflectance of epitaxial films deposited onto the (111) face of GaAs. He noted that most of the peaks in the reflectance spectrum occurred at the same wavelengths as those for the hexagonal form, although the peak at 7.12 eV (0.174 μm) was missing, and the one at 5.49 eV (0.226 μm) was not split, as it was in the hexagonal case. No values of n and k are available for cubic cadmium sulphide.

Gallium Antimonide (GaSb)

DAVID F. EDWARDS and RICHARD H. WHITE
University of California
Lawrence Livermore National Laboratory
Livermore, California

Few reports can be found in the literature of the fundamental optical properties of GaSb. Research-sized crystals are relatively easy to grow, but GaSb has developed little technical interest. Aspnes and Studna [1] report n and k values calculated from pseudo-dielectric functions measured by spectroscopic ellipsometry. They call this the pseudo-dielectric function because no corrections were made for possible surface overlayers or subsurface damage effects. For surfaces free of these defects or by making the appropriate corrections, the ellipsometric measurements would give the "true" dielectric function. In either case they calculate the n and k values from the ellipsometric measurements.

As pointed out by Aspnes and Studna [1], three recent technical advances have been made that allow for more accurate determination of the optical properties of semiconductors, GaSb included. The first and most important is the development of their new etching and cleanup procedures [2]. These procedures minimize the thickness of the undesirable surface layer that forms on semiconductors. As a result, their ellipsometric measurements and calculated pseudo-dielectric functions more accurately represent the intrinsic bulk values. The second advance is the development of the automatic spectroscopic ellipsometer. This instrument determines both components of the complex pseudo-dielectric function over a broad spectral range. No wavelength extrapolations are needed as in the Kramers–Kronig analysis of reflectance data. The third is the development of unambiguous criteria for optically determining the best surfaces. These "best" surfaces are the ones most free of roughness, unintentional overlayers, absorbed contaminants, and subsurface damage. Aspnes and Studna have been leaders in this field of the ellipsometric determination of the optical properties of solids.

Several reports have been made of the reflectance in the near-UV and visible regions. Seraphin and Bennett [3] list the reflectance data of Cardona [4] for the 4–0.5 eV spectral range. Tauc and Abraham [5] report reflectance for the same spectral region. The objective of both reports was

an investigation of the band structure of GaSb, and no extraction of n and k values was made.

Johnson, Filinski, and Fan [6] measured the absorption coefficient in a p-type undoped GaSb sample at 1.7 K in the region of the intrinsic energy gap. ($E_g = 0.8100$ eV at 1.7 K). They observed three sharp bands. The highest energy band (0.8100 eV) they identify as due to an exciton absorption. The two bands of lower energy (0.8049 eV and 0.7958 eV) they attribute to exciton-impurity complexes. They report their data in a curve of absorption coefficient (cm^{-1}) as a function of photon energy. From their curve we have extracted the k values. The three exciton peaks are designated α, β, and γ in Table I.

Edwards and Hayne [7], using the angle-of-minimum-deviation technique, measured the near-IR index of refraction from 1.8–2.5 μm (about 0.7–0.5 eV). Oswald and Schade [8] were among the first to report n and k values for the infrared region. They calculated n and k values from the measured reflectance and transmittance for a GaSb sample with a resistivity of only 0.08 Ω cm. This small resistivity and the monotonically increasing k values with wavelength indicate free-carrier absorption. As a result, the Oswald and Schade data are not given in the table that follows. Wynne and Bloembergen [9] calculated the indices of refraction at 5.3 μm and 10.6 μm from the measured transmittance and coherence length for second-harmonic generation in GaSb with a CO_2 laser. These data are not included in our tabulation because of the inconsistencies with the data of other sources and the lack of precision of their method for extracting index values.

Hass and Henvis [10] measured the fundamental lattice reflection bands of several III-V compound semiconductors including GaSb. These measurements were made at liquid-helium temperature using a grating spectrometer for increased spectral resolution. By comparing the observed reflectance spectrum with that calculated using a single classical oscillator [11], they obtained the "best" values of the oscillator parameters. From these parameters we calculated the n and k values for the 29–100 μm spectral region.

Pikhtin and Yas'kov [12] report a semi-empirical method for calculating the dispersion of the refractive index using three adjustable parameters associated with the energy-band structure. For those materials where extensive data are available, their predictions accurately fit the indices. For GaSb they use the data of Refs. [7] and [8], which do not have the spectral breadth necessary for the accurate determination of their three parameters. Test calculations [13] for wavelengths longer than those of Ref. [7] indicate the values of the indices are sensitively dependent on the values of these adjustable parameters. It appears that indices over a broad spectral range are needed to improve the accuracy of the Pikhtin–Yas'kov calculated data for GaSb.

The indices of refraction and extinction coefficients for GaSb are given in Table I and plotted in Fig. 1. Most of the data are for room temperature except where noted. The n and k values from 6.0 eV to 2.1 eV are the measured data of Aspnes and Studna [1]. The k values for the absorption-edge region are calculated from the measured absorption coefficients of Johnson *et al.* [6]. The n values from 2.0 eV to 0.0443 eV (0.62–28 μm) were calculated from a Herzberger-type dispersion formula fit to the measured data of various references [1, 7, 10]. These same data were also fit to a modified Sellmeier-type dispersion formula. This was done for convenience to the reader, but the Sellmeier values are not given in Table I. A total of 28 data points were used for these fittings. As seen in Fig. 1, the indices between 6.0 eV and 2.1 eV (0.2067 μm and 0.5905 μm) do not lend themselves to Herzberger- or Sellmeier-type, curve-fitting routines.

The Herzberger-type dispersion formula [14] is

$$n = A + BL + CL^2 + D\lambda^2 + E\lambda^4,$$

where $L = 1/(\lambda^2 - 2.8 \times 10^6)$ with the wavelength λ in Å, and 2.8×10^6 is the square of the mean asymptote for the short-wavelength abrupt rise in index for 14 materials (GaSb not included) [14]. For the 28 points from 0.62 μm to 28 μm, and room temperature, the coefficients are

$$A = 3.850787$$

$$B = 2.024481 \times 10^7$$

$$C = 1.079226 \times 10^{15}$$

$$D = -4.397689 \times 10^{-11}$$

$$E = 3.527494 \times 10^{-19}.$$

The RMS error between the reported indices and the values calculated from the dispersion formula is 0.192%.

For the reader's convenience, the modified Sellmeier-type dispersion formula [15] is

$$n^2 = 1 + A/(\lambda^2 - B) + C\lambda^2/(\lambda^2 - D),$$

where the wavelength λ is in Å. For the 28 data points, the coefficients are

$$A = 3.779678 \times 10^{-8}$$

$$B = 1.558825 \times 10^{-9}$$

$$C = 1.266738 \times 10^{1}$$

$$D = -1.013537 \times 10^{-9}.$$

The RMS error is 0.226%.

In Table I the n and k values from 29 μm to 100 μm were calculated from the lattice band parameters of Ref. [10] and are for liquid-helium temperature. These calculations were extended beyond the range of measurement to 100 μm, in order to estimate ε_0, the low frequency dielectric constant. Hass and Henvis [10] report $\varepsilon_o = 15.69$ compared with $n^2 = 15.98$ at 100 μm.

Cardona [16] reports the measured temperature coefficient of the refractive index of GaSb to be

$$\frac{1}{n}\frac{\mathrm{d}n}{\mathrm{d}T} = 8.1 \pm 0.2 \times 10^{-5}\,\mathrm{K}^{-1}$$

for the 5–10 μm spectral region. This coefficient was determined from changes in the interference patterns produced by multiple internal reflections in single crystals with low impurity concentrations. He reports that the results are independent of free-carrier effects for the temperature range of about 85–415 K.

Ghosh *et al.* [17] have developed a simple model for predicting the temperature and pressure coefficients of the refractive index of some zinc-blende semiconductors, GaSb included. They predict the temperature coefficient at constant pressure to be

$$\left(\frac{\mathrm{d}n}{\mathrm{d}T}\right)_{\mathrm{P}} = 1.47 \times 10^{-4}\,\mathrm{K}^{-1}$$

at 3.7 μm for the range −173–127 °C. They compare this with experimental values of $3.11\text{–}3.05 \times 10^{-4}\,\mathrm{K}^{-1}$. Their predicted pressure coefficient is

$$-\left(\frac{\mathrm{d}n}{\mathrm{d}P}\right)_{\mathrm{T}} = 44.5 - 52.8 \times 10^{-3}\,\mathrm{GPa}^{-1}.$$

They have no experimental data for comparison nor do they give a wavelength or pressure range.

Silicon–Germanium Alloys (Si_xGe_{1-x})

J. HUMLÍČEK, F. LUKEŠ, and E. SCHMIDT
Department of Solid State Physics
Masaryk University
Brno, Czechoslovakia

Silicon and germanium form a continuous series of crystalline alloys, Si_xGe_{1-x}, from $x=0$ to $x=1$. Optical constants of both constituents have been critiqued extensively by Potter [1] and Edwards [2] in *HOC I*. Optical response of the alloy varies continuously over the entire range of compositions x, providing a suitable degree of freedom in tailoring the material for possible optical applications. On the other hand, the alloy is a very good object for physical studies of disorder-induced effects in electron and phonon structure of crystalline solids. It has also been studied in order to understand better the electron band structure of the pure constituents. In spite of numerous studies devoted to this alloy system, the number of papers allowing reasonable extraction of the optical constants is somewhat limited.

In the present critique, we compile the optical data for three compositions, representative of Si-rich ($x\approx0.80$), Ge-rich ($x\approx0.25$), and nearly-equal-content ($x\approx0.50$) alloys. This particular choice was influenced by the requirement of nearly coinciding compositions for data available from various sources. With one exception, we did not interpolate the composition dependence at fixed wavelengths to match the chosen values of x; instead, we have tabulated the original data obtained for slightly different compositions. It should be pointed out that the three spectra are a rather limited data base with respect to possible accurate interpolation for other alloy compositions. Data are listed in Table I and plotted in Fig. 1.

Early measurements of the energy position of the intrinsic optical absorption edge were reported in 1954 by Johnson and Christian [3]. The near-infrared absorption spectra were subsequently studied in detail by Braunstein *et al.* [4] in wide ranges of composition and temperature. Bulk samples were single crystals in the range of 0–20% and 90–100% Si;

intermediate compositions were polycrystals. The alloy composition was determined by spectrographic techniques to ±5% of the content of silicon (for 0–70% Si) or germanium (for 70–100% Si). Fluctuations in composition between slices from the same ingot are mentioned; consequently, the spectra of absorption coefficient α were taken on the same sample thinned progressively from 500 to 5 μm. Higher values of α might be influenced by the inferior quality reported for some of the thinnest alloy samples. Special care was taken to ensure that all the light transmitted through the sample was collected on the detector. This indicates problems with scattered light, which we also mention below in the discussion of phonon spectra. Room temperature was specified to be 296 K; this is fairly important, since the band edge shifts strongly with temperature. The refractive index needed for calculations of α from measured transmittances was obtained from the transmission at long wavelengths.

The extensive work of Braunstein *et al.* [4] provides no spectra for the representative compositions of 25%, 50%, and 80% Si; therefore, we used their results in the following interpolation scheme. The absorption coefficient was fitted in Ref. [4] to the Macfarlane–Roberts expression:

$$\alpha(E, T) = A\left[\frac{(E - E_g - k\theta)^2}{1 - \exp(-\theta/T)} + \frac{(E - E_g + k\theta)^2}{\exp(\theta/T) - 1}\right], \tag{1}$$

where E is the photon energy, $k\theta$ the phonon energy (k is the Boltzmann constant, not to be confused with the extinction coefficient), E_g the energy gap, T the temperature, and A a temperature-independent factor. The first term in square brackets of Eq. 1 is to be included for $E > E_g + k\theta$, the second for $E > E_g - k\theta$; $\alpha = 0$ below $E_g - k\theta$. A detailed compositional dependence of the best-fit values of $E_g(x)$ and the phonon equivalent temperature $\theta(x)$ is given by Braunstein *et al.* [4]. We have read their room-temperature spectra from graphs and determined the remaining parameter A that fits them best with appropriate values of E_g and θ. Interpolated values of all of the three parameters were inserted in Eq. 1 to generate the $\alpha(E)$ spectra for $T = 296$ K. We have limited the spectral range so as to obtain the α values from 1 to 1000 cm^{-1}. The corresponding extinction coefficient is shown in the tables. The results of the interpolation procedure agree to about ±20% with values obtained by interpolating the experimental spectra either in compositions for fixed photon energies or vice versa. Because of the smoothing action of Eq. 1, the precision of the tabular data is limited only by the three decimals shown. The accuracy, however, is probably much lower. A factor-of-two difference, which is rather typical of various sources for pure Si and Ge [1, 2], is probably hard to achieve in the case of an alloy.

Reflectance measurements in the spectral range of strong absorption above the band gap, aiming at the identification of several interband thresholds, were performed by Tauc and Abrahám [5]. Schmidt [6] measured the reflectance in the energy region from 1–13 eV on a number of alloy samples. Three of them had compositions suitable for our tabulation. The compositions were determined by X-ray diffraction; the mean error of x was ± 0.004. The polycrystalline samples were mechanically polished and chemically etched. The thickness of surface oxides was estimated ellipsometrically to be between 2 and 4 nm. No correction was performed for the overlayers. The optical constants were computed from Kramers–Kronig (K–K) relations, using a combination of exponential (13–18 eV) and constant (above 18 eV) extrapolation of the reflectance. The K–K analysis of these data was repeated with a modified extrapolation, and the accuracy of the dielectric functions was tested for pure Si and Ge by Humlíček *et al.* [7]. We tabulate the room-temperature (300 K) results of the latter K–K computations for selected photon energies. Since the low values of the extinction coefficient k at the red side of the spectral region are very unreliable, only values where $k>0.4$ are given.

Very recently, ellipsometry has been used to measure the optical response from 1.66–5.7 eV by Humlíček *et al.* [8]. Two series of samples were studied. Bulk polycrystals were Syton-polished; no polishing was used for single-crystal epitaxial layers. The epilayers were strain-free; the lattice mismatch was relaxed by misfit dislocations extending less than about 100 nm into the layers of total thickness of several micrometers. All samples were measured under flowing dry nitrogen, after a wet chemical treatment was used to remove the surface overlayers. The alloy compositions were determined from the energy position of the strong E_1 interband threshold; the mean error of x was about ± 0.003. The accuracy of the dielectric functions was estimated by examining trends in the data at fixed wavelengths as a function of alloy composition for 20 different samples. In spite of the care taken to avoid both surface damage and overlayers, the surface quality was found to be the limiting factor in the accuracy. In the nine spectra selected for tabulation in Ref. [8], the errors of both real and imaginary parts of the dielectric function are estimated to be a few tenths throughout the whole composition and spectral range. We have not tabulated the uncertain values of k less than 0.3 on the low-energy side of the ellipsometric spectra, because of the poor accuracy and precision of the method in this case [8].

There is a fairly good agreement of the reflectance and ellipsometric results in the energy position of all spectral structures. In particular, the E_1 absorption edge shifts from 2.1 eV in Ge to 3.4 eV in Si; this offers a convenient way to determine accurately the alloy composition, provided the bowing of the concentration dependence is taken into account [8]. A slight blue shift of the reflectance spectrum of Table I b with respect to the

ellipsometric one in the region around 2.7 eV is due to the difference of the compositions. The systematic trends in the differences of both sets of n and k are obviously due to the thicker surface films in the reflectance measurements. The refractive indices agree to two figures in the near infrared. The agreement of extinction coefficients above 5 eV is also satisfactory. The most pronounced failure of the reflectance data is the systematically lower values of n on the high-energy side of the overlap with the ellipsometric spectra. The discrepancy becomes more pronounced for Ge-rich alloys, in accordance with increasing optical thickness of the overlayers with increasing Ge content.

For both Ge and Si, refractive indices in the transparent region below the intrinsic absorption gap were measured with high precision by angle of minimum-deviation and channel-spectra techniques [1, 2]. We have not found analogous data for the alloys, obviously because of the problems in obtaining sufficiently homogeneous crystals of high optical quality. We have chosen the values based on the reflectance measured by Schmidt [6]. The R values were fitted with refractive coefficients given by the polynomial

$$n(E) = n_0 + n_1 E^2 \tag{2}$$

for the photon energy E from 1–1.5 eV, neglecting extinction indices k. The two coefficients n_0 and n_1 were determined from the least-squares fit for each alloy composition. The extrapolation of Eq. 2 below 1 eV is tabulated here. The values are probably accurate to a few hundredths, as indicated by a reasonable agreement of the results for pure Si and Ge.

Infrared lattice absorption in the alloys has been measured by Braunstein [9] throughout the whole range of compositions. However, most of his spectra for a silicon content of 22–81% showed a strong background absorption due to free carriers. Cosand and Spitzer [10] studied the lattice modes for Ge-rich ($x \leqslant 0.12$) and Si-rich ($x \geqslant 0.88$) alloys in the wavenumber region from 100–700 cm^{-1}. They identified two-phonon bands analogous to those of pure Si and Ge. In addition, several temperature-independent bands are interpreted as being due to single-phonon processes. The latter are not seen in perfect homopolar lattices of Si and Ge, since the single-phonon excitations produce no dipole moment. Unpublished spectra of Humlíček [11] were measured in the 180–1500 cm^{-1} range at 300 K. The samples were of p-type conductivity with about 10^{15} free holes per cm^3. No Drude-like background is observable for this low level of doping. The alloy compositions (determined from spectral positions of the E_1 interband thresholds [8]) are fairly close to the three target values of the present tabulation. The observed transmission in the transparent region above 1500 cm^{-1} was found to be lower than the

value predicted by reflection losses of the thick slab of nonabsorbing material:

$$T|_{k=0} = \frac{1-R}{1+R}, \qquad R = \left(\frac{n-1}{n+1}\right)^2, \tag{3}$$

where n is the refractive index. This is obviously due to the scattering of the probing beam by inhomogeneities in the composition, which prevents a part of the transmitted light from reaching the detector. The tabular k values were obtained from the transmittances normalized to the maximum value of Eq. 3 in the region above 1500 cm^{-1}. For $x = 0.8$, two strong peaks near 400 and 480 cm^{-1} emerge; they are related to the analogous bands observed for Si-rich alloys by Cosand and Spitzer [10]. For higher Ge content, the band near 400 cm^{-1} dominates the absorption spectrum with peak values of the absorption coefficient, $\alpha = 4\pi k/\lambda$, above 10 cm^{-1}. The phonon absorption is related to inevitable spectral variations of the refractive index. However, the magnitude of the changes from any smooth dispersion curve of the Eq. 2 type is expected to be less than a few thousandths, as found for silicon by Humlíček and Vojtěchovský [12]. Because of the rich spectral structure changing strongly with the composition, this spectral region is most difficult for dealing with the wavenumber- and composition-dependent extinction coefficients.

[a]The reference from which the values were extracted is given in brackets next to the first value. The nominal alloy compositions are: x=0.246 [6], x=0.250 [8], x=0.250 obtained by interpolating the data of Braunstein et al. [4], x=0.260 [11].

TABLE I(b)

Values of n and k for Si_xGe_{1-x}, $x = 0.50$, from Various References[a]

eV	cm^{-1}	μm	n	n	k	k
12.8		0.09686	0.75 [6]		0.81 [6]

[a]The reference from which the values were extracted is given in brackets next to the first value. The nominal alloy compositions are: x=0.551 [6], x=0.487 [8], x=0.500 obtained by interpolating the data of Braunstein et al. [4], x=0.450 [11].

[a]The reference from which the values were extracted is given in brackets next to the first value. The nominal alloy compositions are: x=0.803 [6], x=0.782 [8], x=0.800 obtained by interpolating the data of Braunstein et al. [4], x=0.800 [11].

Lead Tin Telluride (PbSnTe)

H. PILLER
Louisiana State University
Baton Rouge, Louisiana

There are many alloys of $Pb_{1-x}Sn_xTe$. We can tabulate data only for a very few on the Pb-rich side. Also, it is not possible to find the same x value over a wide spectral range. The reflectivity of the lead-salt narrow-gap alloy PbSnTe was studied by Korn and Braunstein [1, 2]. Measurements of near-normal reflectivity were made at room temperature in the photon-energy range of 0.5–13 eV. Czochralski-grown p-type bulk samples were used in the measurements. Samples were cut, ground, and hand-polished to produce optical-quality surfaces. After an electrochemical etch, samples were immediately placed in a vacuum (at least 10^{-5} torr), and spectral scans were begun. Consistent results were obtained upon repreparation of sample surfaces. The maximum estimated absolute reflectance error throughout the spectral range was at most 2%. The optical constants n and k were obtained through a Kramers–Kronig computation. $Pb_{1-x}Sn_xTe$ can be grown throughout the range $0 \leqslant x \leqslant 1$. PbTe and SnTe both crystallize in the rocksalt structure, and both have interband optical transitions at the L point in the Brillouin zone. The width of the direct energy gap changes with the composition of the alloy; as x increases, the band gap first decreases and then increases. The optical constants are listed in Table II. Columns 4 and 5 show n and k for $x = 0.17$ and columns 6 and 7 for $x = 0.09$. Both samples were p-type single crystals. Values of n and k for $x = 0.19 \pm 0.02$ are plotted in Fig. 1.

Drabkin *et al.* [3] measured the variation of the absorption coefficient in $Pb_{1-x}Sn_xTe$ for $x = 0.2$ and $x = 0.1$ with carrier densities $n_e = 8 \times 10^{17}$ and $n_p = 2.5 \times 10^{18}\ cm^{-3}$, respectively. The measurements were made in the photon-energy region 0.2–0.8 eV. The data were obtained from epitaxial films at 300 K. The films were single crystals. The lattice constants of the films were identical with the constants of the bulk samples, which shows that the evaporation did not alter the composition. The thicknesses of the samples were 1.92 and 1.48 μm, respectively. The k data were calculated from the absorption coefficients given in the graph [3], which are readable to three figures. The corresponding k values for $x = 0.2$ and $x = 0.1$ are

listed in Table II (columns 5 and 7) and k for $x=0.2$ is plotted in Fig. 1. Good agreement with experiment was found by calculating the data from a two-band Kane model. The following energy gaps were used in the calculations: 0.207 eV for $x=0.2$ and 0.25 eV for $x=0.1$.

McKnight and El-Rayess [4] measured the far-infrared reflectivity of films of indium-doped $Pb_{1-x}Sn_xTe$ from 40–240 cm^{-1}. The films were grown from sources with $x=0.21$ and 0.25 on BaF_2 substrates. The measurements were made at 300, 150, 80, 25, 20, 15, and 8 K. Both samples were doped with In at levels above 0.5 atomic percent. In "sufficiently doped" samples, the indium centers pin the Fermi level by binding carriers usually present because of deviations from metal-chalcogenide stochiometry. The sample with $x=0.21$ was estimated to be 15 μm thick and the sample with $x=0.25$ was 19 μm thick. Data were ratioed versus a coin-silver mirror of near-unit reflectivity. Multiple runs were made and the data averaged to achieve a standard deviation of about 1%. A fit to the reflectivity of the $x=0.21$ sample at 300 K was made assuming a film dielectric function, based on a classical two-oscillator (plasmon–phonon) model of the following form:

$$\varepsilon(\omega)=\varepsilon_\infty\left[\frac{(\omega_L^2-\omega^2)}{(\omega_T^2-\omega^2-i\Gamma\omega)}\right]-\frac{\omega_P^2}{\omega(\omega+i/\tau)}.$$

Here ω_T and ω_L are the transverse and longitudinal optical phonon frequencies, respectively. ω_P is the plasma frequency. A very good fit to the experimental reflectivity was obtained with the following parameters: $\omega_T=32\ cm^{-1}$, $\omega_L=111\ cm^{-1}$, $\omega_P=402\ cm^{-1}$, $1/\tau=88.4\ cm^{-1}$, $\Gamma=17.2\ cm^{-1}$, $\varepsilon_\infty=42.5$. The carrier concentration was estimated to be below $10^{17}\ cm^{-3}$. We calculated the optical constants n and k from the dielectric constant using the parameters given above. These data are listed in Table II. A smooth plot of the n and k data is given in Fig. 1.

McKnight and El-Rayess [5] measured also the far-infrared reflectivity of indium-doped $Pb_{1-x}Sn_xTe$ films with $x=0.25$ and $x=0.21$ under high hydrostatic pressure. The measurements were made in the region 50–200 cm^{-1}. The primary effect of the hydrostatic pressure is to decrease the band gap by about 7.4 meV/kbar. An increase in the plasma frequency was observed with increasing hydrostatic pressure. This is consistent with the observed large relative decrease in the narrow band gap and hence the effective mass. Carrier freeze-out and semi-insulating behavior was observed at low temperatures.

Takaoka *et al.* [6] measured the far-infrared magnetoplasma spectra in 1 at.% indium-doped $Pb_{1-x}Sn_xTe$ single crystals across the band-inversion region between $x=0.15$ and 0.40 at temperatures between 4.2 and 20 K. They observed that the band-edge masses and the energy gaps seem not to reach zero at the band-inversion tin composition ($x=0.35$) [7].

Takaoka and Murase [8] observed the local vibration mode of indium atoms in $Pb_{1-x}Sn_xTe$ at 160 cm^{-1} by far-infrared absorption measurements.

Dornhaus *et al.* [9] reviewed the optical properties, including dielectric properties and phonon spectra. The dielectric properties of the mixed-crystal $Pb_{1-x}Sn_xTe$ were extensively investigated. They are characterized by large static and optical dielectric constants. Lehmann *et al.* [10] measured the dielectric properties of epitaxial $Pb_{1-x}Sn_xTe$ layers in a range between $x=0$ and 0.225 at 9 GHz. Their results show that the static dielectric constant (ε_s) does not depend on the effective band gap. The authors measured $\varepsilon_s=230$ in an n-type sample with $x=0.2$ with a carrier concentration of 2×10^{17} cm^{-3} at 300 K and $\varepsilon_s=1850$ with a carrier concentration of 0.14×10^{17} cm^{-3} at 77 K. The temperature dependence of the static dielectric constant and of the TO phonon energy was investigated in many experiments, including neutron scattering experiments [9].

Table I is a summary of the n and k data for various values of x. We have plotted n and k only for $x=0.19\pm0.02$ over the widest possible spectral range, thus omitting plots for other x values in Table II.

Mercury Cadmium Telluride ($Hg_{1-x}Cd_xTe$)

P. M. AMIRTHARAJ
U.S. Army Center for Night Vision and Electro-Optics
Fort Belvoir, Virginia

Mercury cadmium telluride is a II-VI ternary alloy semiconductor that belongs to the zinc-blende family and hence has much in common with other, better known semiconductors such as GaAs and InP. The overall shape of the dielectric functions ε_1 and ε_2 are similar for most of the materials of the same family, but the precise energy positions of the various spectroscopic features vary from one material to the other. The uniqueness of $Hg_{1-x}Cd_xTe$ arises from the fact that the direct gap can be varied all the way from $0(x \simeq 0.15)$ to 1.6 eV ($x = 1$). The band gap can therefore be reduced below the lowest limit attainable within the III-V family. Hence, $Hg_{1-x}Cd_xTe$ has found widespread use in the fabrication of quantum infrared detectors and is currently the leading candidate. In order of technological importance, it is perhaps next only to Si and GaAs.

The optical properties of $Hg_{1-x}Cd_xTe$ has been investigated by many investigators ever since the very first reported study by Lawson *et al.* [1]. However, the main thrust of the early work was in using spectroscopic features for obtaining information regarding the electronic band structure. Hence, the photometric accuracy available in the reports on the measurement of reflection and transmission spectra was limited, and consequently, the precision of the optical constants determined is not completely satisfactory. More recent investigations, particularly using scanning ellipsometry, have yielded optical data with substantially improved accuracy.

One must also take note of the advances in materials technology. The more recent reports of absorption measurements performed on epitaxial films with well-controlled properties, in particular x and its uniformity, are clearly more dependable than the earliest reports. Hence, values compiled in this review are weighted toward the more recent papers and those that are expected to possess greater intrinsic accuracy. Comparisons to earlier work are made where warranted; the remaining earlier studies are referenced without an evaluation of the dependability and accuracy of the data.

The review by Dornhaus and Nimtz [2], the compilation of several parameter values by Brice and Capper [3], and the comprehensive collection of n and k values of CdTe by Palik [4] are earlier works to which the reader is referred for additional information. Table I displays a summary of the data included in this review, and Fig. 1 shows a graphical plot of the variation of n and k for one representative alloy composition, namely $x = 0.2 \pm 0.01$. The complex forms of the dielectric function, ε, and the refractive index, $\mathbf{n}$, the absorption coefficient α and the reflectivity R are reproduced below for later reference:

$$\varepsilon = \varepsilon_1 + i\varepsilon_2 \tag{1}$$

$$\mathbf{n} = n + ik \tag{2}$$

$$\mathbf{n} = \sqrt{\varepsilon} = \sqrt{(\varepsilon_1 + i\varepsilon_2)} \tag{3}$$

$$R = |(\mathbf{n}-1)/(\mathbf{n}+1)|^2 = \{(n-1)^2 + k^2\}/\{(n+1)^2 + k^2\} \tag{4}$$

$$\alpha = 4\pi k/\lambda. \tag{5}$$

The units of energy (E), frequency (ω), and wavelength (λ) throughout this review will be eV, cm^{-1}, and μm, respectively.

The Ultraviolet, Visible, and Near-Infrared Range (6–1.5 eV)

The most complete and dependable set of ellipsometric measurements in the near-ultraviolet, visible, and near-infrared region on $Hg_{1-x}Cd_xTe$ have been reported by Arwin and Aspnes [5] and Viña *et al.* [6]. Arwin and Aspnes [5] measured ε_1 and ε_2 in the visible and near-visible energy region from 6–1.5 eV of crystalline HgTe, $Hg_{0.8}Cd_{0.2}Te$, $Hg_{0.71}Cd_{0.29}Te$ and CdTe. The samples were prepared by zone refining and were n-type. A detailed investigation was undertaken of the surface modifications introduced by the most commonly used chemical treatment, namely etching in a solution of Br_2/CH_3OH as well as other etching procedures. A residual layer of amorphous Te (α-Te), approximately 7 Å thick, was observed to be present on the Br_2/CH_3OH-treated surfaces. Figures 1 and 2 in Ref. [5] display the values of ε_1 and ε_2 corrected for the presence of the overlayers; an electronic computer record provided by Aspnes [7] was used to calculate the n and k values shown in Table II. The presented values are rounded off to three decimal places. Some variation can be seen in the last significant digit due to random noise. The overall absolute accuracy is ~2%. However, the ability to calculate third derivatives (to simulate electroreflectance data) suggests that the precision or relative accuracy is significantly better than that.

The ellipsometric measurements of Viña *et al.* [6] reported the ε_1 and ε_2 values for seven values of x: 0, 0.2, 0.43, 0.76, 0.86, 0.91, and 1.0. The samples were grown by the traveling-heater method using Te as a solvent, and sample surfaces were prepared using a chemomechanical polish of Br_2/CH_3OH. ε_1 and ε_2 were measured in the 5.5–1.7 eV energy region. Large figures provided by Cardona [8] were digitized using an electronic digitizer, the n and k values were computed, and they are displayed in Table III for all except the $x = 0.2$ sample. The digitization error in ε_1 and ε_2 is expected to be $\pm 1\%$ or ± 0.02, whichever is greater. The worst errors are likely to occur in the vicinity of the zero crossing of ε_1 and at the smallest values of k. Values for the endpoint binaries, HgTe and CdTe, are included for completeness as well as to provide the reader with a standard of comparison. The numerical procedures for correcting the data for the presence of the α-Te overlayer has been discussed by Aspnes and Arwin [9] and may be carried out where warranted.

For HgTe, the n and k values presented in Table III agree with those in Table II to better than ~3%, except for the k values at the lowest energies, which deviate by ~10%. The CdTe values, on the other hand, display a maximum deviation of ~10% for both n and k. In addition, a comparison of the values of Viña *et al.* [6] with those obtained from Arwin *et al.* [10] that were not corrected for the presence of the surface α-Te layer indicates a deviation of only ~5%, half of that for the previous comparison. Hence, at least part of the disagreement between the values quoted in Table II and III is probably due to the ~7 Å-thick surface α-Te layer. The n and k values in Table III are both more accurate for HgTe than for CdTe. For x values of 0.43, 0.76, 0.86, and 0.91, the values presented in Table III are likely to be reliable to better than ~3% for the low-x value; however, the error for the high-x samples may be as high as ~10% in the worst case.

The first scanning ellipsometric measurements for HgTe were reported by Moritani *et al.* [11]. Their uncorrected n and k values deviate approximately 10% from those in Table II; the corrections attempted by them to account for a thin overlayer actually make the deviation much larger. The n and k values for CdTe were compiled earlier by Palik [4]. The values for the 1.5–4.9 eV range were obtained from the ellipsometric results of Marple and Ehrenreich [12] and the reflection and transmission investigation of Myers *et al.* [13]. Marple and Ehrenreich's [12] results agree to within ~3% of those in Table II for n in the near-infrared and visible range of 1.5–3.2 eV but deviate by as much as 15% in the higher energy ultraviolet region, that is, 3.2–4.9 eV; the opposite seems to hold for k, with the UV values agreeing to better than ~10% but deviating much more for the visible and near IR. Both the n and k values of Myers *et al.* fall within 10% of those of Table II.

Single-wavelength measurements of ε_1 and ε_2 have been reported by Korsak *et al.* [14] for the He–Ne laser wavelength of 0.6328 μm for the

following x values: 0, ~0.16, 0.2, ~0.29, ~0.65, and 1.0. These measurements were conducted using ellipsometry with chemomechanically polished samples; allowance was made for a naturally occurring native-oxide layer. The graphs presented in the paper were digitized and n and k values calculated for all but the $x = 0.2$ sample, whose values were quoted in the paper; they are presented in Table IV. The n values, where a direct comparison could be made, agree to better than ~3% with those in Table II; the k values for the endpoint binaries, HgTe and CdTe, agree within ~10%, but those for the alloys indicate large differences, being greater than a factor of two for $x = 0.29$.

The dominant shape of the variation of ε_1 and ε_2 with the energy is determined by transitions between the various electronic bands. The main spectroscopic features in the 6–1.5 eV range are labeled E_1, $E_1 + \Delta_1$ and E_2. The variation of these transitions with the Cd mole fraction, x, have been investigated by Viña *et al.* [6] and are reproduced below:

$$E_1\,(\text{eV}) = (2.147 \pm 0.005) + (0.44 \pm 0.02)x + (0.7 \pm 0.1)x^2 \tag{6}$$

$$E_1 + \Delta_1\,(\text{eV}) = (2.778 \pm 0.005) + (0.47 \pm 0.02)x + (0.6 \pm 0.1)x^2 \tag{7}$$

$$E_2\,(\text{eV}) = \pm(4.468 \pm 0.003) + (0.66 \pm 0.01)x - (0.06 \pm 0.08)x^2. \tag{8}$$

The E_2 feature has been shown to comprise four transitions [5]. However, these can be resolved only in the derivative spectra [5] and not directly in the shape of ε_1 and ε_2.

Reflectivity measurements have been conducted for both the endpoint binaries and the alloy for energies above 6 eV, but no published results of Kramers–Kronig analysis exists. As noted earlier, the driving force behind the reflectivity measurements was the understanding of the electronic band structure, and hence the photometric accuracy of the results is less than that required to extract reliable n and k values. However, a short review of the reflectivity analysis is presented in the interest of completeness.

Room-temperature reflectivity measurements up to 22 eV have been reported by Cardona and Greenaway [15]. The measurements were performed on cleaved bulk crystals of CdTe and HgTe; the difficulty of obtaining crystals that were of sufficient size and flatness in the case of HgTe led to an error that could be as large ±10%. Shay and Spicer [16] have reported reflectivity measurements on CdTe in the 6–10 eV range. Low-temperature reflectivity for HgTe and CdTe measured at 10 and 15 K, respectively, in the 2.5–8 eV range has been published by Chadi *et al.* [17]. For the alloy, reflectivity measurements have been performed by Rodzik and Kisiel [18] in the energy range of 2–8.5 eV for the following thirteen alloy x values: 0, 0.02, 0.04, 0.095, 0.12, 0.155, 0.35, 0.37, 0.47, 0.5, 0.58,

0.62, and 1.0; the measurements were conducted in the 115–300 K temperature range, and the temperature coefficients of the various critical-point energies were computed.

The Band-Edge and Subband-Gap Region (~1.5 E_g–0.1 eV)

The energy region in the vicinity of the direct gap has, by far, commanded the most attention due to its obvious importance in electro-optic device applications. The dependence of the energy gap, E_g, on the alloy composition x has been reviewed by Hansen *et al.* [19], and more recently by Seiler *et al.* [20]. The relationship between E_g and x from Ref. [19], which is valid for the entire range of x for the temperature range 4.2–300 K, is given below:

$$E_g(x) = -0.302 + 1.93x + 5.35(1-2x)(10^{-4})T - 0.81x^2 + 0.832x^3. \quad (9)$$

The standard error in the calculation was estimated to be 0.013 eV [19]. A modification of the above equation that more accurately represents $E_g(x)$ for $0.2 \leqslant x \leqslant 0.3$ for low temperatures has been proposed in Ref. [20] and is shown below:

$$E_g(x) = -0.302 + 1.93x + 5.35(1-2x)(10^{-4})[(-1822 + T^3)/(255.2 + T^2)]$$
$$- 0.81x^2 + 0.832x^3. \quad (10)$$

A large number of infrared absorption measurements have been reported for the alloy beginning with the first report by Lawson *et al.* [1]. This review is limited to the more recent efforts, particularly those that report n and k and those for which a reasonable estimate of n can be carried out using the interpolation procedure described in the next section.

Many of the infrared optical studies in $Hg_{1-x}Cd_xTe$ have been limited to an analysis of the details of the absorption mechanisms and consequently report only the absorption coefficient, $\alpha(E)$. Fortunately, however, some exceptions exist. Kucera [21] has measured the value of n in the subband-gap energy region extending down to ~0.045 eV for x values of 0.18, 0.292, 0.39, 0.397, 0.459, 0.461, 0.522, and 1.0 at 80 and 300 K using the spacing of the interference fringes. Samples used in the study were grown using the Bridgman technique and annealed in Hg vapor to produce n-type conductivity except for the endpoint binary, CdTe, which was p-type and grown using a directional-freezing procedure. The observed n values at 300 K

were computer-fitted to the Sellmeier form with two resonances as shown:

$$n^2(\lambda) = a_0 + a_1/(1-(a_2/\lambda)^2) + a_3/(1-(a_4/\lambda)^2), \tag{11}$$

where λ is the wavelength in μm.

The parameters determined from the computer fit are presented in Table V. An interpolation procedure was also established to express the empirical x dependence of each of the parameters in Eq. 12 as shown below:

$$a_i = A_i + B_i x + C_i x^2. \tag{12}$$

The values of A_i, B_i, and C_i determined from a computer fit are presented in Table VI. In addition, Kucera [21] has measured the dispersion of n at 80 K and analyzed both the 80 and 300 K data using the semiempirical theory of Pikhtin and Yaskov [22]. Jensen and Torabi [23] have calculated the value of n from first principles for the whole alloy range, $0 \leqslant x \leqslant 1$. The calculations agree with the interpolated values of Kucera [21] to within ~3% for both high x values and low energies but deviate by 10% for energies close to the band gap for the low x alloys. The reader is referred to Refs. [21–23] for further details.

The behavior of n and k has been investigated by Finkman and Nemirovsky [24] for $0.205 \leqslant x \leqslant 0.220$ and by Finkman and Schacham [25] for $x = 0.29$ and 1.0. The refractive index was established using the interference fringes at energies below E_g, and the absorption coefficient in the vicinity of E_g was measured using straightforward reflection and transmission studies. The samples used were grown using the solid-state recrystallization method or the Bridgman technique and were n-type with carrier concentrations in the range of 1×10^{15} to 3×10^{15} cm^{-3} and mobilities in the range of 0.3×10^5 to 1×10^5 cm^2/Vs; the CdTe sample was semi-insulating. The x value was measured to an accuracy of better than ± 0.005.

The values of n were computer-fitted to a modified Sellmeier form with a λ^2 and a λ^4 correction term as shown below:

$$n^2(\lambda) = a_0 + a_1/(1-(a_2/\lambda)^2) + c\lambda^2 + d\lambda^4, \tag{13}$$

where λ is the wavelength in μm. The values of the parameters a_0, a_1, a_2, c, and d for $x = 0.205$, 0.29, and 1 are presented in Table V. The authors estimate the error in Eq. 13 to be less than ±2% and ±0.5%, respectively, for the absolute and relative values. The change in n when the temperature was reduced from 300 K to 80 K is estimated to be less than 3% [24, 25]. A comparison between the values reported by Finkman and Schacham [25]

and those obtained from Kucera [21] for $x = 0.29$ shows that the latter is systematically lower by ~1% for energies up to $\sim 0.75E_g$, above which it is lower by as much as 3%.

The dispersion of n is less than ±1% for the energy range $\sim 0.75E_g \leqslant E \leqslant 0.1$ eV for $0.29 \leqslant x \leqslant 0.522$ and for the energy range $\sim 0.5E_g \leqslant E \leqslant 0.1$ eV for CdTe. Hence, a consideration of the mean value of n in this region, namely n_{av}, is appropriate. A computation of n using the results from Refs. [21] and [25] and a computer fit, with the condition that the variation with x be monotonic, leads to the following simple empirical relationship:

$$n_{av} = 2.65 + 1.17(1-x)^2 \qquad 0.29 \leqslant x \leqslant 1. \tag{14}$$

The estimated errors are approximately ±2%. Values calculated using Eq. 14 for x ranging from 0.3–1 are displayed in Table VII; these values are lower by 5–8% than $\sqrt{\varepsilon_\infty}$ determined from the far-infrared measurements of Baars and Sorger [26].

Absorption measurements for HgTe, the endpoint binary, which is semimetallic with a band gap of ~ -0.3 eV, have been reported by Szuszkiewicz [27] in the 0.05–0.625 eV region. Optical measurements were conducted at 10 K using thin sample plates 10 μm thick, obtained by crystallization of HgTe on an Hg solution. The samples were further thinned using chemical etching. Figures provided in Ref. [27] were digitized, and the k values calculated are displayed in Table VIII; a constant value of 3.74 was assumed for n in calculating the absorption coefficient from the measured reflection and transmission spectra.

The absorption coefficient, $\alpha(E)$, in the vicinity of E_g was also studied by Finkman and Nemirovsky [24], Finkman and Schacham [25], and Schacham and Finkman [28] in the temperature range of ~85–300 K for the same samples used for determining n. The behavior of $\alpha(E)$ below the band gap was described by a modified form of the Urbach rule [24, 25] as shown:

$$\alpha(E) = \alpha_0 \exp[\sigma(E - E_0)/w] \tag{15}$$

$$w = T + T_0. \tag{16}$$

T is the lattice temperature of the specimen, and the parameters α_0, σ, E_0, and T_0 were determined using a computer fit to the measured $\alpha(E)$. For $x = 0.205$, the values of α_0, σ, E_0, and T_0 are 4×10^{-5} cm^{-1}; 5.65 K/cm^{-1}; 263.3 cm^{-1}, and 80.5 K, respectively [24]. A simultaneous computer fit to

two samples with $x = 0.215$ and 0.29 led to the following empirical dependence of the various parameters on the alloy composition, x [25]:

$$\alpha_0 = \exp(53.61.x - 18.88) \tag{17a}$$

$$E_0\,(\text{eV}) = 1.838.x - 0.3434\ \text{eV} \tag{17b}$$

$$\sigma(K/\text{eV}) = 3.267 \times 10^4 (1+x) K/\text{eV} \tag{17c}$$

$$T_0(K) = 81.9K. \tag{17d}$$

At energy values exceeding the band gap, direct optical transitions will occur between the valence and conduction bands. The large values of $\alpha(E)$ exceeding $10^3\,\text{cm}^{-1}$ require the use of very thin samples, and hence, relatively few results have been reported [28, 30]. However, Schacham and Finkman [28] have established the following approximate simple relationship to describe the behavior of $\alpha(E)$:

$$\alpha(E) = \beta(E - E_g)^{1/2} \tag{18a}$$

$$\beta = 2.109 \times 10^5 [(1+x)/(T+81.9)] \tag{18b}$$

with the band gap, E_g, being defined as that energy at which $\alpha(E) = 500\,\text{cm}^{-1}$ with Eq. 18a valid for $\alpha(E) > 800\,\text{cm}^{-1}$. The estimated values compared favorably for $E_g = 0.15$ eV with the theoretical calculation based on the Kane model by Anderson [29]. The values of E_g from $\alpha(E) = 500\,\text{cm}^{-1}$ deviate by ~10 meV from those calculated using Eq. 9 [25]. The values of $\alpha(E)$, and hence k, were calculated for $x = 0.205$ and 0.29 using the appropriate parameter values for the Urbach region and estimated for the band-to-band region up to $1.5E_g$ using the relationship shown in Eq. 18a. These k values along with the value of n for $x = 0.205$ and $x = 0.29$ are displayed in Tables IX and X, respectively, for temperatures of ~80 and 300 K; the values of E_g given in Refs. [24, 25] are indicated in the tables.

In the case of p-type samples and samples at high temperatures with a significant hole density, the intervalence-band transitions between the light- and the heavy-hole bands will cause additional absorption and hence a larger value of k. The values of k for $E \geqslant E_g$ and n are not likely to be affected significantly. Mroczkowski and Nelson [31] and Mroczkowski *et al.* [32] have reported $\alpha(E)$ for p-type samples with x values of 0.2 and 0.3 and acceptor density in the range of 1.2×10^{17} to $2.8 \times 10^{17}\,\text{cm}^{-3}$. Bulk samples grown using a quench-anneal process were thinned and transmission and reflection measurements made to establish the absorption

coefficient. Figures provided in Ref. [31] were digitized and interpolated to determine the appropriate values of k; they are presented in Tables IX and X for $x=0.2$ and 0.3, respectively. For energies below the fundamental gap, E_g, the k values in p-type samples are significantly larger than those in n-type samples.

Chu *et al.* [30] have also reported $\alpha(E)$ results for the $x=0.2$ value at 300 K. Compared with the values from Ref. [24], their values of $\alpha(E)$, and hence k, are twice as large for $E>E_g$ and nearly an order of magnitude greater at 0.12 eV. The lack of well-defined standards for measuring x and E_g as well as sample differences make it difficult to explain the disagreement. However, the k values presented in Tables IX and X are probably reliable only up to a factor of two. As indicated earlier, a comparison between the n values reported by Finkman and Schacham [25] and those obtained from Kucera [21] for $x=0.29$ shows that the latter is systematically lower by ~1% for energies up to $\sim 0.75E_g$, above which it is lower by as much as 3%.

The absorption behavior for $E \leqslant E_g$ can also be affected significantly by other sample-dependent properties: the presence of a large density of free electrons will affect the band edge through the Burstein–Moss shift [33], which is particularly important in small-band-gap $Hg_{1-x}Cd_xTe$. Chu *et al.* [33] have investigated the influence of the Burstein–Moss effect in samples with $0.165 \leqslant x \leqslant 0.194$ and electron density in the range of 0.4×10^{17} to $7 \times 10^{17}\ cm^{-3}$. For energies lower than E_g, free-carrier absorption will also play a part as shown by Qian *et al.* [34]; their absorption coefficient for a sample with $x=0.19$ and free-electron density of $7 \times 10^{17}\ cm^{-3}$ and impurity density of $3.4 \times 10^{18}\ cm^{-3}$ ranged from ~30 to ~200 cm^{-1} in the 9–15 μm wavelength region. Optical transitions between energy levels associated with impurity levels may also influence the k values in the subband-gap region.

The n values are not likely to change significantly with the electronic properties. For high temperatures approaching 300 K and above, the intrinsic carriers are likely to dominate [2], and hence, the optical absorption will be influenced by both the Burstein–Moss effect and the intervalence-band mechanisms.

The n and k values obtained at 300 K for $x=0.443$ are presented in Table XI. The k values were obtained by digitizing the appropriate $\alpha(E)$ curve provided in Ref. [30], and the value of n was calculated using the interpolation procedure established by Kucera [21].

Far-Infrared and Reststrahlen Region (0.05–0.0001 eV)

The optical behavior in the far-infrared (FIR) and reststrahlen region is determined by the lattice oscillations, free-carrier properties, impurity transitions, and band-to-band transitions in the narrow-gap alloys. Of these, the free-carrier and impurity-related behavior are extrinsic and can

vary significantly from sample to sample. Hence, the optical constants reported are confined to those determined at low temperatures using reflection spectroscopy, where the free-carrier and impurity contributions are expected to be small. Methods of estimating the free-carrier contribution and references to both free-carrier and impurity-related FIR investigations are provided for further information.

The FIR reflectivity spectrum of HgTe was studied by Grynberg *et al.* [35] in the frequency range extending from 80–250 cm^{-1} at temperatures ranging from 8–300 K. The samples were crystalline slabs, approximately 60 μm in thickness and were fabricated using liquid-phase deposition by slow cooling of Te in an Hg bath. At 4.2 K the samples were *n*-type with free-carrier densities and mobilities of $\sim 6 \times 10^{15}$ cm^{-3} and $\sim 6 \times 10^{5}$ cm^2/Vs, respectively. The dielectric function was determined using the Kramers–Kronig (K–K) analysis. The low-temperature values of n and k reported in Table XII were determined from digitized values of the $\mathrm{Im}(\varepsilon)$ and $\mathrm{Im}(-1/\varepsilon)$ curves presented in Ref. [35]. The approximate positions of the zeros in $\mathrm{Re}(\varepsilon)$ were estimated from the theory and the values of various parameters provided in Ref. [35]. The limited accuracy available in the procedure described confines the range of n and k to 110–161 cm^{-1} which overlaps the reststrahlen region extending from the transverse optical (TO) phonon frequency at ~ 118 cm^{-1} to the longitudinal optical (LO) phonon frequency at ~ 139 cm^{-1} [36]. Grynberg *et al.* have described the FIR behavior using a model of $\varepsilon(\omega)$ that accounts for the band-to-band transitions in addition to the well-known free-carrier and lattice-oscillation contributions. The functional form of the latter two are discussed in the following paragraphs.

The FIR reflectivity spectrum measured at a temperature of ~5 K and the associated K–K analysis results for *n*- and *p*-type samples with $x \simeq 0.21$ have recently been reported by Amirtharaj *et al.* [37]. The samples were grown using the solid-state recrystallization method, which usually yields *p*-type crystals; conversion to *n*-type was induced using an Hg vapor annealing procedure. The free-carrier densities were $\sim 4 \times 10^{17}$ and 3×10^{14} cm^{-3} in the *p*- and *n*-type samples, respectively, at low temperatures. The reflectivity spectrum measured in the 10–400 cm^{-1} frequency range was analyzed using the K–K procedure to determine the optical constants n and k presented in Table XII. The large differences in the values of n and k between the *n*- and *p*-type samples are expected to be due to the presence of the hole plasma, intervalence-band transitions, as well as possible impurity transitions in the *p*-type samples.

In samples with a large value of x and low impurity and hole density, the band-to-band and intervalence band transitions as well as impurity-related transitions can be neglected. In this case, the FIR behavior can be satisfactorily described using the well-known classical form shown below [38]:

$$\varepsilon(\omega) = \varepsilon_\infty + \Sigma_j\{S_j(\omega_j)^2\}/\{(\omega_j)^2 - \omega^2 - i\omega\Gamma_j\} - (\omega_p)^2\varepsilon_\infty/\{\omega(\omega + i/\tau)\}, \quad (19)$$

where ω is the frequency and the lattice oscillations are treated as damped oscillators with strength S_j, frequency ω_j, and damping Γ_j, and ε_∞ is the value of $\varepsilon(\omega)$ at frequencies much larger than the lattice oscillations in the absence of free carriers. The last term describes the contribution of the free carriers, where ω_p is the plasma frequency and τ is the scattering time. ω_p and τ are related to the free carrier density, N, and mobility, μ, through the following relations:

$$\omega_p = 4\pi Ne^2/m^*\varepsilon_\infty \quad (20a)$$

$$\tau = \mu m^*/e, \quad (20b)$$

where m^* is the effective mass of the charge carrier and e its electronic charge.

Shen and Chu [39] have analyzed the FIR reflectivity of an $x = 0.45$ sample using the classical form of $\varepsilon(\omega)$ shown in Eq. 19. The reflection spectrum was measured at a temperature of 35 K in the frequency range of 50–210 cm^{-1}. Seven lattice oscillators with the following parameters were used to computer fit the spectrum with all the observed fine structure: ω_j, S_j, Γ_j,

(1) 110 cm^{-1}, 0.3, 10 cm^{-1}
(2) 123 cm^{-1}, 5.6, 2.8 cm^{-1}
(3) 134 cm^{-1}, 0.7, 9 cm^{-1}
(4) 141 cm^{-1}, 0.15, 6 cm^{-1}
(5) 149 cm^{-1}, 0.9, 4 cm^{-1}
(6) 153 cm^{-1}, 0.35, 6 cm^{-1}
(7) 157 cm^{-1}, 0.15, 4 cm^{-1}.

The 110 cm^{-1} feature has been assigned to a two-phonon process. The HgTe- and the CdTe-like TO phonons occur at 123 and 149 cm^{-1}, respectively. The fine structure in the measured spectrum described by the remaining oscillators has been tentatively assigned to originate in optically active vibrational modes of the various combinations of anions and cations in the alloy lattice. The value of ε_∞ needed to fit the measurements is ~16. The values of n and k determined using Eq. 19 and the parameters mentioned above are displayed in Table XIII along with $\sqrt{\varepsilon_\infty}$ reported by Baars and Sorger [26].

The values of n and k for alloy compositions where the band gap occurs above the FIR region can be estimated if the lattice-oscillator and free-

carrier parameters are known. The two main optical phonons, namely the CdTe- (TO_1 and LO_1) and the HgTe-like (TO_2 and LO_2) phonons, have been investigated using both FIR reflectivity and Raman scattering by many investigators [2, 26, 40–43]. The variation of the optical phonons with x, the Cd mole fraction, is nearly linear. The CdTe-like phonons, TO_1 and LO_1 converge to $\sim 152\ \text{cm}^{-1}$ as x approaches 0, which is the frequency of the local vibrational mode of Cd in HgTe; and the HgTe-like modes, TO_2 and LO_2, converge to $\sim 131\ \text{cm}^{-1}$ at $x = 1$, which is the gap mode related to Cd oscillations in HgTe [40]. Talwar and Vandevyer [40] have used a random-element isodisplacement model to describe the x dependence of the optical phonons, and the fitted values of the various parameters may be found in Ref. [40].

Absorption due to electronic transitions associated with impurities at energies below the reststrahlen region has been reported by Scott [44] and Dornhaus [45]. Impurity-related vibrational features have been investigated by Talwar and Vandevyer [40], and Shen and Chu [46] have measured low-frequency absorption and interpreted it as originating in impurity- and disorder-activated phonons.

Conclusion

The optical constants, n and k, of the semiconducting alloy, $Hg_{1-x}Cd_xTe$, have been reviewed. Since $Hg_{1-x}Cd_xTe$ has been known and investigated only since 1959, the relevant published literature is less extensive and thorough than that of Si and GaAs. However, the technological importance of $Hg_{1-x}Cd_xTe$ is well recognized, and hence, it is hoped that this review is timely and will be helpful to researchers as well as engineers who are mainly concerned with the design and production of electro-optic devices.

The values of n and k included have been confined to the more recent reports and those that are, in the author's opinion, more reliable. Although a reasonable effort was made to study and evaluate all the published literature, inadvertent omissions are possible, particularly with papers published in languages other than English. The lack of measurements in the 1.5 eV to $\sim 1.5\ E_g$ energy region is a significant absence and needs to be addressed.

ACKNOWLEDGMENTS

The author wishes to thank Dr. D. E. Aspnes of Bellcore, Redbank, N.J., U.S.A. for the electronic record of ε_1 and ε_2 data and Prof. M. Cardona of the Max Planck Institute,

Stuttgart, Germany, for the expanded figures from Ref. [6]. The assistance provided by Mr. E. Kelso of the U.S. Army Center for Night Vision and Electro-Optics with the literature search is gratefully acknowledged.

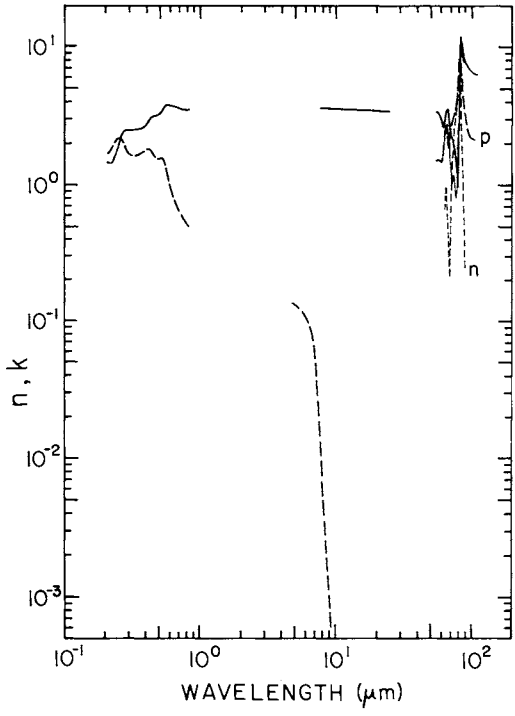

Fig. 1. Log–log plot of n (solid line) and k (dashed line) versus wavelength in μm are for $Hg_{1-x}Cd_xTe$ with $x=0.2$. The ultraviolet, visible, and near-infrared data are for $x=0.2$, n-type at room temperature. The IR data in the vicinity of E_g and lower energies are for $x\simeq 0.2$, n-type at room temperature. The far-infrared data are for $x=0.21$ at 5 K, n- and p-type. Free-carrier effects appear minimal in the n-type data.

TABLE I

Values of n and k of $Hg_{1-x}Cd_xTe$ – Synopsis of x values included in this review

x	UV, Visible and Near IR (6 - 1.5 eV)	Band Edge and Subband gap (~$1.5E_g$ - 0.1 eV)	Far Infrared and Reststrahlen (~0.05 - ~0.001 eV)
0	X	X	X
0.16	X[a]		
0.18		X[b]	
0.20	X	X	
0.205		X	
0.21			X
0.29	X	X	
0.292		X[b]	
0.3		X	
0.39		X[b]	
0.397		X[b]	
0.4		X[c]	
0.43	X		
0.443		X	
0.45			X
0.459		X[b]	
0.5		X[c]	
0.522		X[b]	
0.6		X[c]	
0.65	X[a]		
0.7		X[c]	
0.76	X		
0.8		X[c]	
0.86	X		
0.9		X[c]	
0.91	X		
1.0	X	X[c], Ref. [4]	Ref. [4]

[a] Measurements were made at the He-Ne laser wavelength of 0.6328 μm.
[b] n was measured in the subband gap region and computer fitted to the Sellmeier equation [21].
[c] Average values of n for the subband gap region ($0.75E_g$ to 0.1 eV) computed using an interpolation routine are presented.

TABLE II

Values of n and k for $Hg_{1-x}Cd_xTe$ (Ref. [5])

			x=0		0.20		0.29		1.0	
eV	cm^{-1}	μm	n	k	n	k	n	k	n	k

0.459	7.919	0.6816	1.843	3.414	75.80		
0.461	7.802	0.6968	1.820	3.418	76.14		
0.522	7.310	0.8223	1.413	2.209	67.74		
0.205[b]	12.33	0.2167	6.568			-1.102×10^{-3}	-3.065×10^{-7}
0.29	10.91	0.3437	3.752			-9.661×10^{-4}	-1.956×10^{-8}
1.0	5.304	1.899	0.5713			-4.188×10^{-4}	-2.391×10^{-7}

[a] The first seven values for $0.18 \leq x \leq 0.522$ are from Ref. [21].
[b] The next three values for x=0.205, 0.29 and 1.0 are from Ref. [26].

TABLE VI

Quadratic Interpolation Sellmeier Coefficients

	A_i	B_i	C_i
a_0	19.76	-41.82	34.5
a_1	0.373	-0.281	2.153
$a_2(\mu m)$	-200.0	2.841	1.897
a_3	18.79*	-58.4*	52.41*
$a_4(\mu m)$	73.25*	73.25*	73.25*

* The mean value of 73.25 μm was used.

TABLE VII

n_{av} – Mean Value of n for the Subband-Gap Region in $Hg_{1-x}Cd_xTe$ – 300K[a]

x	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
n_{av}	3.22	3.07	2.94	2.84	2.76	2.70	2.66	2.72

[a] n_{av} values are computed using interpolation procedure described in the section on the visible and near visible behavior and are valid for the energy range $0.75E_g \leq E \leq 0.1$ eV for $0.3 \leq x \leq 0.5$ and for $0.5E_g \leq E \leq 0.1$ eV for $0.5 \leq x \leq 1$

TABLE VIII

Values of n and k for HgTe – 10K (Ref. [27])

eV	cm^{-1}	μm	n	k

Selenium (Se)

EDWARD D. PALIK
Institute for Physical Science and Technology
University of Maryland
College Park, Maryland

The trigonal form of Se is birefringent with an optical c axis. Light polarized perpendicular to c is termed ordinary (o), and light polarized parallel to c is termed extraordinary (e). This leads to one of the applications of Se for second-harmonic generation of IR light [1, 2]. Se is a direct-band-gap semiconductor ($E_{g\perp} = 1.98$ eV; $E_{g\parallel} = 2.11$ eV). In addition to the IR spectrum (to be discussed), the Raman spectrum has been studied in some detail [3, 4]. A good collection of many of the properties of Se is given in Ref. [5].

The room-temperature n and k values chosen in this critique are listed in Table II. These are plotted in Fig. 1.

Starting at the long wavelength of 3.3 cm, permittivity measurements have been done by Sicha *et al.* [6] using a cavity-resonance method. A rectangular resonator with a TE_{101} mode had a resonance frequency of $\sim 9.1 \times 10^9$ Hz ($\sim$3.3 cm). A needle-shaped Se crystal with c along the long direction was inserted at a point of maximum electric-field intensity, and the change of resonant frequency was measured. Some analysis of the resonant frequency as a function of electric field across the cavity, depolarization factor for $\mathbf{E} \| c$, and ε for polycrystalline material, finally yielded $\varepsilon_\parallel = 9.3$ and $\varepsilon_\perp = 8.0$. These numbers prove to be in poor agreement with reststrahlen-data analysis and extrapolation ($\varepsilon_{o\parallel} = 12.2$, $\varepsilon_{o\perp} = 7.4$), and we do not weight them heavily. Other data of Salo *et al.* [7] give $\varepsilon_\parallel = 21$ and $\varepsilon_\perp = 11$, also much different. It seems that reflectivity to long wavelength (100–1000 μm) is a better way to determine ε_o as long as the free-carrier concentration is low. This question of the free-carrier contribution to the low-frequency dielectric function is important to consider and should be answered, based on the measured free-carrier concentration and conductivity.

Danielewicz and Coleman [8] have collected several sets of data in the spectral range 10–10^4 cm^{-1}, and we have used these as a basis set of data, adding other data for comparison and overlap. The extinction-coefficient

ISBN 0-12-544422-2

data are extracted from absorption-constant data for the multiphonon region [9]. The fundamental transverse optic phonon absorption was obtained from a Lorentz-oscillator fit of the reststrahlen reflectivity. Similar results were obtained by Lucovsky *et al.* [10] and Geick *et al.* [9]. All these workers used equivalent models, except that Danielewicz and Coleman used UV interband oscillators to account for ε_∞ better. In their notation,

$$\varepsilon = \varepsilon_1 - i\varepsilon_2 = (n - ik)^2 = 1 + \sum \frac{Se_j ve_j^2}{ve_j - \nu^2} + \sum \frac{So_j vo_j^2}{vo_j - \nu^2 + i\gamma_j \nu},$$

but we have omitted their free-carrier term. Note that they have chosen the negative sign in defining ε. Se_j and So_j are the strengths for electronic and vibrational oscillators, respectively, for each polarization. ve_j and vo_j are the resonant frequencies for the electronic and vibrational oscillators, respectively, for each polarization. γ_j is the phonon line width (damping constant) for each polarization. We list these parameters in Table I.

The oscillator fit was used to calculate n from 10,000–10 cm^{-1}, but the near-IR data of Gampel and Johnson [11] are implicit in the tabulation. This fit also provided the k values in the vicinity of the phonon frequencies $v_T(\perp) = 140$ and $v_T(\|) = 102\ cm^{-1}$ but did not consider the multiphonon absorption.

Measurements of the IR refractive index by minimum-deviation and interference-fringe techniques yielded values from 3.2–3.7 for $n_\|$ and 2.5–2.9 for $n_\perp$, suggesting material and sample-preparation problems. We accept the values given by the fit of Danielewicz and Coleman, which are essentially those of Gampel and Johnson [11]; the results of Caldwell and Fan [12] are in reasonable agreement to one unit in the first decimal place; the results of Gobrecht and Tausend [13] are within two units in the first decimal place. Although the data of Ref. [13] fill in a gap from 1.0–0.7 μm, we have not tabulated it because it fails to join on to n values at either end. Gampel and Johnson discuss such variations in n among several groups.

Henrion [14] has measured the transmission of thin-plate samples at various temperatures between 400 K and 90 K. Analysis of α versus hv yielded a straight line indicating a direct band gap $E_{g\|} = 2.11$ eV and $E_{g\perp} = 1.98$ eV at 300 K. Exponential tail absorption at lower energy was shown to be due to charged impurities.

Several reflection experiments have been performed at and above the fundamental band gap [15, 16]. Absorption peaks have been correlated to band-structure calculation. The Kramers–Kronig (K–K) analysis of such data in the 4–14 eV region by Leiga [15] and in the 2–5 eV region by Tutihasi *et al.* [16] have been combined for Table II. Tutihasi *et al.*

performed standard reflection experiments from cleaved/acid-etched surfaces using Glan-prism linear polarizers. Prisms of silica and flint glass were used in the monochromator. The reflection standard was an Al mirror.

Leiga used a vacuum UV monochromator with hydrogen, neon, or helium discharges as the light source. Only cleaved or as-grown surfaces were used because chemical etching affected the reflectivity results. The angle of incidence was 20°. Two types of samples were used: one with the c axis perpendicular to the surface and one with the c axis in the surface. Measurements (with the partially polarized light from the monochromator) on both kinds of samples for two positions of each sample 90° apart (about the incident-beam direction) could be algebraically unsorted to give $R_\perp$ and $R_\parallel$. K–K analysis involved some assumptions and use of other researchers' data to cover the entire spectrum.

Bammes *et al.* [17] used synchrotron radiation to measure reflectivity from 3–30 eV for samples with the c axis in the plane. Since the synchrotron radiation was nearly linearly polarized to start, and further linearly polarized by a premirror and grating, the sample/detector could be rotated to change the angle of incidence and the sample could be rotated to measure $\mathbf{E} \perp c$ and $\mathbf{E} \parallel c$. This, along with the work of Liega, dramatically illustrates how to do polarization experiments when there are no polarizers at high photon energies!

The ε_1 and ε_2 dielectric-function data were plotted in small figures, which had to be expanded in order to read the values. Therefore, in addition to the errors in measuring R and performing K–K analysis, there are now errors due to graph reading. Since peaks are well-defined in the ε versus eV plots, however, we keep two to three significant figures for n and k to show the peaks in most instances.

We have found no data above 30 eV until the absorption edges are reached. Since X-ray scattering cross-sections have been determined for many elemental materials, we have used the model of Henke *et al.* [18] to calculate n and k from 4–250 Å. The X-ray absorption edges as listed in Ref. [19] are K(12.654 keV), L_1(1.652 keV), L_2(1.474 keV), L_3(1.434 keV), M_5(0.05443 keV), and most of these appear in Fig. 1 (remember the conversion factor 8065.48 cm^{-1}/eV). Still-lower-energy transitions are merged into the band structure. Although there is no overlap with the data of Bammes *et al.*, extrapolation of both sets of data toward each other seems to be feasible.

ACKNOWLEDGMENTS

We thank W. R. Hunter for calculating optical constants in the X-ray region. V. Saile kindly provided unpublished data in the visible–UV regions.

Lincoln, Nebraska

The optical constants of 6H SiC were presented by Choyke and Palik in *HOC I* [1]. The purpose of the present critique is to present optical constants of high-quality, large-area, cubic β-SiC epitaxially grown films on (100) polished silicon wafers. This epitaxy and the advance in associated technology is a relatively recent development [2, 3] and permits electronic application using these materials. Optical-properties measurements taken so far include those in Refs. [4] and [5].

There are early references to properties of various polymorphs of SiC including bulk-grown cubic SiC that may interest the reader. Most of the references were given in [1], with additional ones listed elsewhere [6–10].

Cubic SiC films were grown on silicon substrates by S. Nishino, J. A. Powell, and others using the technique described in Refs. [2–4]. Briefly, buffer layers were formed on heated Si substrates by flowing hydrocarbon gas and hydrogen over the surface. Then crystalline SiC was grown by flowing silane, hydrocarbon, and hydrogen. Table I contains original, unpublished data, taken by variable-angle spectroscopic ellipsometry (VASE) on samples grown by J. A. Powell. Measurements at up to five angles of incidence were used for each wavelength. A model of a single film on a substrate was used, thus ignoring the possibility of an interface between the film and the substrate or of an overlayer. The refractive index of these (cubic) materials was assumed to be isotropic.

Results on two samples are reported here: a thick film (of order 10 μm), and a film approximately 6000 Å thick. For the spectral range given, the

ISBN 0-12-544422-2

extinction coefficient, $|k|$, <0.02, which is the lower limit measurable by ellipsometry. Cubic SiC has an indirect optical band gap of approximately 2.3 eV. At 3500 Å the absorption coefficient is $3 \times 10^3\,\text{cm}^{-1}$ [5], corresponding to an extinction coefficient of <0.01, below the limit of reliable measurement by ellipsometry. Thus, the data in the table below are given down to 3500 Å.

Errors in index of refraction of the thick film were ±0.01, whereas for the 6000 Å film, errors were ±0.03. The results generally agree with the data reported for n_O of the 6H phase in Ref. [1]. The values of n reported for the thick film were lower than n_O [1] by 1%; the results for the 6000 Å film were higher than n_O in [1] by 1 to 3%. The 6000 Å film results for n were nearer to the values of n_e reported in [1].

The growth of polycrystalline β-SiC films on Si was accomplished by Spitzer *et al.* [11, 12] as early as 1959. They deposited the films on Si (heated to 1300 °C) from a gas mixture. The infrared properties were determined by study of transmittance and reflectance. Although data were obtained from 1–15 μm, we stress only the lattice-vibration region 10.5–15 μm. An oscillator fit [11, 12] yielded the parameters $\rho = 0.263 = (\omega_L^2 - \omega_T^2)\varepsilon_\infty / 4\pi\omega_T^2$, $\gamma = 0.0107 = \Gamma/\omega_T$, $\nu_O = 2.38 \times 10^{13}$ cycles/sec (12.60 μm, $\omega_T = 793.6\,\text{cm}^{-1}$), $\varepsilon_\infty = 6.7$; these are essentially the same as those obtained for αII-SiC (hexagonal) [12, 13] for reststrahlen reflection fits only. While the value of γ given here for β-SiC differs substantially from the one given in HOC I for αII-SiC ($\gamma = 0.006$, $\Gamma = 4.75\,\text{cm}^{-1}$), the effect on n and k is small except within $\omega_T \pm 5\,\text{cm}^{-1}$, where it can be as large as +30%. Therefore, the optical constants given by Choyke and Palik [1] for the ordinary ray (virtually the same as for the extraordinary ray) should suffice as a good first approximation for β-SiC. Note the definitions of the oscillator model parameters in Refs. [1, 11, 13].

$k < 0.01$ over the entire spectral range.

Tellurium (Te)

EDWARD D. PALIK
Institute for Physical Science and Technology
University of Maryland
College Park, Maryland

Te has been studied in some detail because
(1) it has a small band gap (0.335 eV, comparable to that of InAs, 0.35 eV, and PbS, 0.45 eV);
(2) this trigonal crystal is birefringent, making it useful as a nonlinear crystal for producing second-harmonic generation by orientation of the index ellipsoid, so that the ordinary index ($\perp$) at the fundamental (say 10.6 μm) can be matched to the extraordinary index ($\parallel$) at 5.3 μm [1];
(3) its band structure is similar to the "classic" III-V compound semiconductor InSb.

Te is a direct-band-gap semiconductor ($E_g = 0.33$ eV), which can be doped to produce free-carrier absorption. When p-doped, interband transitions between the split-off valence band and the heavy- and light-hole bands can be seen peaked at 900 cm^{-1} but covering a broad region of the near IR from 5–20 μm. Good collections of many of the properties of Te are given in Refs. [2, 3].

The room-temperature n and k values chosen in this critique are listed in Table II. These numbers are plotted in Fig. 1. The data were obtained by reading expanded graphs or tables in the original literature or from private-communication data. The references indicated in brackets in the n and k columns pertain down the column until a new reference appears.

Wagner [4] measured the dielectric constants of Te at two wavelengths, 3.2 cm and 8.5 mm, between -170 °C and room temperature. At 3.2 cm a standing-wave, node method was used in which the Te sample was placed at one end of the expandable microwave arm, sandwiched between a crystal-quartz plate and a shorting plate. At 8.5 mm a smaller, more detailed sample holder was used. After some analysis, the following low-temperature values were obtained: at 3.2 cm, $\varepsilon_\parallel = 53$ and $\varepsilon_\perp = 33$; at 8.5 mm, $\varepsilon_\parallel = 55$ and $\varepsilon_\perp = 32.5$. At 3.2 cm there seems to be a slight decrease in ε as the temperature is lowered from room temperature (~13 °C is the highest value from the graphs), then a flattening out. At 8.5 mm there is a

All rights of reproduction in any form reserved.
ISBN 0-12-544422-2

slight rise, then a plateauing or decrease in ε. The conductivity is observed to decrease at the same time. We must conclude that the stated hole concentration of $N = 5 \times 10^{14}\,\mathrm{cm}^{-3}$ puts the plasma frequency $\omega_p = 4\pi Ne^2/\varepsilon m^*$ near 3.6 cm, and these slight variations in ε are indications that the free carriers are freezing out, revealing the dielectric constant of the lattice. (We used $e = 4.77 \times 10^{-10}$ esu, $\varepsilon_\parallel = 55$, $m^* = 0.11(9.1 \times 10^{-28}\,\mathrm{gm.})$) Subsequent use of these (low-temperature, hole-free) $\varepsilon_{\parallel,\perp}$ values as room-temperature data must be kept in mind. All subsequent Te samples in this collection of data will have comparable or larger free-carrier concentrations.

The lattice-vibration region in the far IR from 60–500 cm^{-1} has been measured in reflection and transmission by Geick *et al.* [5] with a Perkin–Elmer Model 301 grating spectrometer (sample at 300 K). Similar work over a shorter spectral range has been done by Lucovsky *et al.* [6], who concentrated on the reststrahlen reflectivity. Both groups fitted their reflectivities with the same type of Lorentz-oscillator model. Although the numbers are similar, some differences occur. More recently, Rautenberg [7] has measured the far-infrared reflectivity at 300 K with a Fourier transform infrared spectrometer. We choose these more recent data as analyzed with the same oscillator model, namely

$$(n - ik)^2 = \varepsilon_1 - i\varepsilon_2 = \varepsilon = \varepsilon_\infty + \frac{\Delta\varepsilon_j \nu_{Tj}^2}{\nu_{Tj}^2 - \nu^2 + i\Gamma_j \nu}$$

for each polarization. ε_∞ is the high-frequency dielectric constant at ~8 μm, ν_T is the transverse optic phonon frequency (cm^{-1}), $\Delta\varepsilon$ is the change in dielectric function upon passing through the resonant frequency from near IR to dc (oscillator strength), and Γ is the phonon damping constant (cm^{-1}). These are listed in Table I. The corresponding parameters of Geick *et al.* and Lucovsky *et al.* ($4\pi\rho = \Delta\varepsilon$ and $\gamma\nu_T = \Gamma$) vary significantly from these in some cases, and we list all three sets of parameters just to illustrate typical differences between laboratories.

The difference in the corresponding parameters indicates that we cannot hope to know n and k to better than one or, at most, two significant figures. Such large differences suggest crystal misorientation, poor polish, or filtering problems for grating spectrometers, all of which would affect R.

We are also confused by the different values of ε_∞ obtained by the three groups, since presumably these numbers are well known in the 5–10 μm region [8, 9], and they should have been used in the fitting process by all the groups. Caldwell and Fan [9] determined $n_\perp = 4.81$ ($\varepsilon_\perp = 23.1$) and $n_\parallel = 6.25$ ($\varepsilon_\parallel = 39.0$) at 8 μm. The fact that $\varepsilon_\parallel$ is as low as 36 suggests that the measured high-frequency reflectivity was too low.

Also of note is the dc dielectric constant obtained from each model: $\varepsilon_{o\parallel}=54.0$ and $\varepsilon_{o\perp}=34.7$ for Geick *et al.*; $\varepsilon_{o\parallel}=45.2$ and $\varepsilon_{o\perp}=30.6$ for Lucovsky *et al.*, and $\varepsilon_{o\parallel}=43.2$ and $\varepsilon_{o\perp}=30.1$ for Rautenberg. These values are to be compared with the values of Wagner: $\varepsilon_{\parallel}=54$ and $\varepsilon_{\perp}=33$. Measurement of reflectivity to 1000 μm is surely the easiest way to determine ε_o.

The region of multiphonon absorption above the fundamental TO frequency has been measured by Grosse and Richter [10] and Geick *et al.* [5]. Both sets of data are similar, but we chose the latter, more complete data as obtained with a Perkin–Elmer spectrophotometer Model 301 at 300 K. Polarization was obtained with polyethylene wire-grid polarizers. The k data as listed in Table II have somewhat less detail than the figures of Ref. [5] because of the coarse grid we used to read the values of the absorption coefficient from expanded graphs. Since the index of refraction was not determined in these measurements, the values listed are from a Lorentz-oscillator fit [7], which ignored this small amount of multiphonon absorption. Note that the values of k for the oscillator fit near ν_T are always less than the measured values of Geick *et al.*, as is to be expected.

The index of refraction has been measured in the near IR from 4–14 μm by Caldwell and Fan [9] using the minimum angle-of-deviation method for a collimated beam passing through an 8°16′ Te prism. However, it was not a single crystal but consisted of several crystallites with boundaries parallel to the c axis. Since the c axis was perpendicular to both the refracting edge and the base of the prism, light could be polarized $\parallel$ and $\perp$ to c for the measurement. Similar prism measurements were done earlier by Hartig and Loferski [8] with Te doped to $p=10^{17}\,\mathrm{cm}^{-3}$. These values, measured to two decimal places, were about 0.04 larger for $n_\perp$ and about 0.05 smaller for $n_\parallel$. This sort of difference could be due to a slight variation of the direction of the c axis, which was supposedly perpendicular to the refracting edge and the base. Note in Fig. 1 that the measured values of n [9] do not join smoothly with the calculated values obtained from the oscillator model [7].

p-Te with $1.25\times10^{17}\,\mathrm{cm}^{-3}$ holes at 300 K shows interband hole absorption (split-off valence band to light- and heavy-hole bands) peaked near $900\,\mathrm{cm}^{-1}$ for $\mathbf{E}\parallel c$ ($\alpha_\parallel=110\,\mathrm{cm}^{-1}$) and much less absorption ($\alpha_\perp=3\,\mathrm{cm}^{-1}$) for $\mathbf{E}\perp c$. We usually would not include such structure because it is extrinsic. However, for $1.7\times10^{15}\,\mathrm{cm}^{-3}$ at 297 K the peak is much smaller and data of Caldwell and Fan are included in Table II because the hole absorption is located just between the multiphonon absorption (which is decreasing to higher frequency) and the band gap absorption (which is increasing to higher frequency). n-Te would not show such absorption.

The absorption in the 5–3 μm region reaches a minimum at 5 μm and begins to increase rapidly at 4 μm as the band gap is neared. The values in this minimum of absorption at 5 μm vary considerably in the literature

depending on whether the material is *n*- or *p*-type; lightly doped *n*-type or *p*-type material with less than $1\times10^{15}\,cm^{-3}$ is desirable to obtain intrinsic results. With such a small band gap, pure Te is expected to be slightly intrinsic at 300 K with electrons as the electrical conductors. As an example, at 5 μm $k_{\|}=4.4\times10^{-4}$ [2], 7.2×10^{-5} [9], 3.7×10^{-4} [11], $<1.1\times10^{-5}$ [12].

The band-edge and higher-energy regions have been studied by several groups by transmission of thin plates [2, 12] and by reflectivity and Kramers–Kronig analysis by Tutihasi *et al.* [12], Merdy [13], and Bammes *et al.* [14]. We have used the data of Tutihasi *et al.* as the basis data (because it represents the lowest free-carrier concentration) over the range 0.3–12 eV, and we have added other sets of data for comparison and overlap. We read expanded graphs of absorption coefficient $\alpha=4\pi k/\lambda$ and ε_1 and ε_2 [12] and calculated *n* and *k*. At the fundamental edge between 0.37 and 0.45 eV, the data of Refs. [2] and [12] obtained from transmission measurements of thin plates are in good agreement. In Ref. [2] there is a table of *n* and *k* over a part of this spectral region (1.4–3.0 eV), presumably obtained from Ref. [12], but it is not exhibited in Ref. [12]. We include both sets of data to illustrate how two separate determinations agree (or disagree). The IR data were obtained with a Leiss monochromator equipped with a LiF prism and a double-plate Si transmission polarizer utilizing Brewster's angle. The UV reflectivity data were obtained with a McPherson 0.5 m monochromator with a 600 line/mm grating blazed at 1500 Å and a biotite plate used as a Brewster-angle reflection polarizer. In the various papers there is considerable discussion of excitons, and direct and indirect gaps; since we are only interested in optical constants, these interpretations are not of primary interest.

Bammes *et al.* have made synchrotron-radiation measurements of reflectivity from 3–30 eV. However, to determine absolute reflectivity, they had to normalize their measurements between 3.5 and 6 eV to the spectra of Tutihasi *et al.* For this reason, we still stress the Tutihasi *et al.* data in Table II. The sample was cleaved with the *c* axis in the sample plane. Since the synchrotron, premirror, and grating each tended to polarize the light linearly, the sample was rotated 90° in its near-normal-incidence position to change from ∥ to ⊥. Peaks in *k* appear to be more clear-cut in the data of Tutihasi *et al.* The overlap of the data of Refs. [7] and [13] is poor, principally in the vicinity of 6 eV.

Since X-ray scattering cross-sections have been determined for many elemental materials above 30 eV, we have used the model of Henke *et al.* [15] to calculate *n* and *k* from 4–250 Å. Since the model takes into account only the number of atoms/cm^3 and not the lattice structure, there is no ∥ and ⊥ designation. The absorption edges of Te [16] are found at *K* (31.811 keV), L_1(4.939 keV), L_2(4.612 keV), L_3(4.341 keV) and most of these appear in Fig. 1. Other broader peaks are made up of many M_3N_1,

$M_4O_{2,3}$, M_3M_5 transitions. Other lower-energy transitions are merged into the band structure. Although there is no overlap with the Bammes *et al.* data, extrapolation of both sets of data until they meet seems to be feasible.

ACKNOWLEDGMENTS

We thank W. R. Hunter for calculating the optical constants in the X-ray region. P. Grosse and V. Saile kindly provided unpublished data in the far IR and VIS–UV regions, respectively.

Tin Telluride (SnTe)

H. PILLER
Louisiana State University
Baton Rouge, Louisiana

The binary compound semiconductor SnTe was found to be isomorphous with rock salt. The nature of chemical binding is mixed ionic–covalent. SnTe has direct interband optical transitions at the L point in the Brillouin zone. The band structure near the fundamental gap is more complicated than in the lead salts. For large hole concentrations one should observe a positive temperature coefficient of the fundamental gap. Optical experiments by Murase *et al.* [1] have shown that the temperature coefficient of the gap changes its sign from negative to positive with increasing hole concentration in the temperature region between 50 and 150 K.

The first detailed study of the reflectivity of SnTe was performed by Cardona and Greenaway [2]. The measurement of reflectivity and absorption of a semiconductor provides a direct method of studying the band structure. Epitaxial layers of SnTe on KCl were used for the reflection and transmission measurements. The SnTe layers were evaporated onto KCl single-crystal substrates, cleaved in air, and held at a temperature of approximately 573 K. X-ray results showed all the films to be single-crystal and to have the crystal orientation of the substrate: (100). No attempt was made to determine the impurity level in the samples. The thickness of the films was determined by the Tolansky interference method. The room-temperature reflectivity should be accurate to a few percent. An analysis of the reflectivity data for SnTe, using the Kramers–Kronig relation, made it possible to make a detailed comparison of the optical constants obtained from both the reflection and transmission results. The absorption constants obtained from the reflection analysis were compared with values obtained from transmission measurements on thin epitaxial films of SnTe. The agreement was shown to be excellent. The quasi-free electron region (plasma region) was also investigated. It was shown that the phenomenological scattering time required to fit the optical constants with the Drude formula [3] is 1.3×10^{-16} sec. The plasma frequency was calculated by taking the density of the valence electrons equal to five electrons per atom.

The room-temperature reflectivity measurements were made over the photon energy range 0.5–20 eV. Measurements of transmission were made in the photon energy range below 4 eV. The optical constants n and k are listed in the first two columns of Table I (n and k). Figure 1 shows a plot of the data.

Korn and Braunstein [4, 5] measured the near-normal reflectivity of polycrystalline SnTe over the photon-energy range 0.5–21 eV at room temperature. The optical constants n and k were determined through a Kramers–Kronig computation. The samples were cut, ground, and hand-polished to produce optical-quality surfaces. After an electrochemical etch, samples were immediately placed in a vacuum (at least 10^{-5} torr) and spectral scans were begun. Consistent results were obtained upon repreparation of sample surfaces. The maximum absolute reflectance error throughout the spectral range was estimated to be at most 2%. The optical constants n and k are listed in Table I (columns 3 and 4). Figure 1 shows a plot of the data.

Burke and Riedl [6] measured the absorption coefficient and the index of refraction of SnTe at 300 K over the photon-energy range between 0.14 and 0.64 eV. The sample was a single-crystal film with a hole concentration of $3.6 \times 10^{19}\,\mathrm{cm}^{-3}$. The single crystal was epitaxially deposited to a thickness of 1.2 μm on an NaCl substrate. The room-temperature data are in good agreement with those obtained by Schoolar and Dixon [7], who measured the optical constants of p-type SnTe at room temperature over the spectral range from 0.1–3.8 eV. The indices of refraction and absorption coefficients were obtained from analysis of normal reflectance and transmittance measurements on epitaxial films ranging in carrier concentration from 3.6×10^{19} to $6.8 \times 10^{20}\,\mathrm{cm}^{-3}$. At photon energies greater than 1.0 eV, the absorption spectrum agrees with the results of Cardona and Greenaway [2]. Electrical, X-ray, and optical data indicate that the films are high quality, single crystals. A "sample in, sample out" procedure was used for taking the data. The error of reflectance and transmittance is estimated to be less than ±3%. The film thickness was determined from analysis of the interference fringes. Such spectra were also used to determine the carrier concentration p from the position of the plasma reflectance minimum. It was estimated that the carrier concentrations determined in this way are accurate to within ±10%. The homogeneity of the films was checked by measuring the reflectance of different areas of the films on both the front and back surfaces. Variations were less than ±3% for all the samples studied. The n and k values determined by Burke and Riedl [6] and Schoolar and Dixon [7] are listed in Table I and plotted in Fig. 1. These, of course, contain the effects of free holes.

Potter [8] made an ellipsometry study of SnTe in the infrared and visible spectral regions. Fukui *et al.* [9] measured the absorption spectra of crystalline SnTe films in the 2–120 eV region using synchrotron radiation at

liquid-nitrogen temperature. In the *in situ* measurements, an SnTe film was evaporated onto a collodion film cooled to about 80 K at a pressure below 10^{-8} torr before the absorption measurements were made. Then the film was annealed at room temperature and then again cooled to 80 K when the measurements were repeated. The absorption spectrum of SnTe in the amorphous and in the crystalline phase was measured. The structure in the absorption spectrum in the crystalline SnTe below 20 eV is in good agreement with previous results [2]. No absorption coefficient was determined from these measurements.

Zinc Selenide (ZnSe)
Zinc Telluride (ZnTe)

L. WARD
Coventry Polytechnic
Coventry, England

In optical terms these two materials have many points in common, and it is therefore proposed to deal with both in the same critique. They are both semiconductors and are members of the II-VI group formed by alloying one element from group II of the periodic table with another from group VI. Their normal crystal structure is face-centered cubic, the zinc-blende or sphalerite type ($F\bar{4}3m$), although it is also possible to grow hexagonal forms of each material (wurtzite structure, C6mc). These materials may be produced synthetically by alloying the two elements in the correct proportions; by chemical vapor deposition (CVP); or by evaporation in vacuum. In making these materials from the basic elements, there is often a tendency for the resulting compound to be zinc-ion deficient and several investigators (for example, Horikoshi *et al.* [1]) have found that this situation may be partially remedied by soaking the boule for several hours in a bath of molten zinc.

In broad terms these two materials each exhibit two main absorption bands. The first of these is in the near-ultraviolet region and arises as a result of electron excitations across the energy gap (about 2 eV) between the broad valence band and the conduction band; the second occurs in the infrared at a wavelength between 40 and 50 μm and is caused by photon resonance with lattice vibrations (transverse phonons). Through the visible spectrum and into the near-infrared region, both ZnSe and ZnTe behave as normally dispersive materials, the refractive indices decreasing monotonically with wavelength; the mean value of n in this region for ZnSe is 2.5, and, that for ZnTe is 2.8. Over the same region, the extinction coefficient, k, is very small for each of the compounds. Consequently, both materials have been used extensively for high-refractive-index optical components and windows. In addition, many of the sets of values of the optical constants that have been published for the visible and near-infrared regions

can be fitted into dispersion equations of the Sellmeier type; over the infrared absorption band, Lorentz equations for $\varepsilon_1 = (n^2 - k^2)$ and $\varepsilon_2 = 2nk$ have also been used successfully. At very short wavelengths there are further absorption bands due to the L and M transitions of electrons in both the elements within each of the compounds. In the X-ray region, the refractive indices approach a value of unity, whereas at very long wavelengths, n is asymptotic to about 3.0 for ZnSe and to 2.9 for ZnTe.

A comprehensive review (up until 1984) of the optical properties of both these materials as well as of zinc sulphide has been given by Li [2], who also presents the results in a variety of graphical forms. In addition, Li lists some of the Sellmeier and Lorentz equations derived by different authors. Tauc [3] has also reviewed the optical properties of semiconductors in the visible and ultraviolet regions and presents tables of the main absorption peaks and their identification with various electron transitions within the Brillouin zone.

Optical Properties of Zinc Selenide

The n and k data selected in this critique are listed in Table I and graphed in Fig. 1. At wavelengths in the X-ray region, 0.0006–0.012 μm, values of n and k may be calculated by the method described by Henke [4] based on the X-ray scattering coefficients, f_1 and f_2, for each element; values of these coefficients are presented in another paper by Henke *et al.* [5]. For ZnSe, $n = 1 - 9.90\lambda^2 (f_{1zn} + f_{1se})$ and $k = 9.90\lambda^2 (f_{2zn} + f_{2se})$, where λ is the wavelength in μm. Over this region, the calculated value of n is close to unity, whereas k shows maxima due to the $L_{II,III}$ transition in Zn (0.0012 μm) and the $L_{II,III}$ transition in Se (0.00085 μm). Values of n and k calculated by Henke's method are listed in Table I.

At short wavelengths (0.01–0.1 μm) the work of Freeout [6], Gautron *et al.* [7] and Cardona and Haensel [8] may be quoted. Cardona and Haensel used evaporated films and made a direct measurement of the absorption coefficient α using radiation from an electron synchrotron, which was dispersed by a Rowland grazing-incidence monochromator and detected by a photomultiplier. k may then be found from the relationship $\alpha = 4\pi k/\lambda$, and n is assumed to be equal to unity; their values of n and k between 0.008 and 0.033 μm are presented in Table I. They found a sharp absorption doublet at 90.6 and 93.35 eV (0.0133 and 0.0137 μm) corresponding to electron transits from the $3p$ level to the conduction band (L) in zinc. A less pronounced peak was caused by the $3d$ to conduction band transition (M) in selenium at 59 eV (0.021 μm). Where there is an overlap in wavelengths, their results are in reasonably good agreement with those calculated by the Henke method. Freeout used synchrotron radiation and a rotary light-pipe scanning reflectometer due to Gerhardt and Rubloff [9] to measure the polarization-dependent reflectance of cleaved single crystals of ZnSe. Analysis by the Kramers–Kronig (K–K) technique enabled him to

produce a graph of ε_2 versus energy, which showed strong structures in the valence-to-conduction-band transition region. Gautron *et al.*, using polished and etched single crystals of ZnSe, measured both the reflectance and the electrolyte electroreflectance; they also employed K–K analysis to extract ε_1 and ε_2, from which n and k may then be calculated over the wavelength range 0.04–1.24 μm. In their experimental technique (see Cardona *et al.* [10]), the specimen is immersed in an electrolyte and dc biased in the blocking direction; a modulating ac voltage is also applied. Monochromatic radiation is then reflected by the specimen to a photomultiplier and both the dc and ac components of the output are recorded. The dc output is proportional to the reflectance; the ratio of ac to dc outputs gives the quantity dR/R, which can be related to ε_1 and ε_2. Their results for n and k, which are also quoted in Table I, match well at the shortest wavelengths with those of Cardona and Haensel, but thereafter and up to 0.02 μm, n remains below 1.0, which behavior differs from that observed by other investigators, for example, Balkanski and Petroff [11]. They were also able to confirm the existence of excitons at room temperature and to correlate features in the reflectance spectrum with different band-to-band transitions within the Brillouin zone. Cardona [12] reported a series of eight peaks in the reflectance spectrum of ZnSe at room temperature between 2.0 and 14.0 eV (0.09–0.62 μm); he was able to correlate all of them with various electron transitions within the Brillouin zone.

Published results over the region of the main energy gap (0.1–0.5 μm) differ among themselves more than those for other wavelength regions; in particular, it is experimentally difficult to make accurate measurements of n and k at the actual absorption edge. Measuring reflectances, Balkanski and Petroff [11] obtained a peak in n of 3.61 at 0.28 μm followed by a minimum of 0.80 at 0.124 μm and then a second maximum of 1.42 at 0.095 μm; k showed peaks at 0.25, 0.18, and 0.13 μm. Aven *et al.* [13] made measurements of the reflectance of single-crystal zinc selenide from 0.1–0.5 μm and used K–K analysis to extract n and k. They found a maximum in n (3.24) also at 0.28 μm with peaks in k at 2.7, 3.15, 4.75, and 5.1 eV (0.459, 0.394, 0.261, and 0.243 μm). The work of Gautron *et al.* [7], which has already been discussed, also extended over the energy gap and up to 1.24 μm. Their peak value for n (2.68) was much smaller than that obtained by other investigators and was found at 0.41 μm, followed by a second maximum (2.57) at 0.31 μm, together with minima at 0.177 and 0.124 μm; k showed maxima at 0.25 and 0.19 μm. The results of Balkanski and Petroff [11] measured between 0.06 and 1.24 μm are considered to be the most reliable of this group and have been chosen to represent this spectral region in Table I.

Over the visible and near-infrared region (0.5–10.0 μm), there have been a large number of measurements of the refractive index, and there is very

good agreement among the various results. The work of Aven *et al.* [13] with single-crystal zinc selenide was extended up to 2.5 μm, and they presented values of ε_1 and ε_2, these being determined from a K–K analysis of the reflectance taken at a temperature of 296 K. From their results, they were able to determine ν_t, the transverse-optical-phonon energy, as 0.026 eV (48.5 μm) and ν_l, the longitudinal-optical-phonon energy as 0.031 eV (40.0 μm); the very-long-wavelength limit of n was calculated to be 2.85.

Thutupalli and Tomlin [14] have also published work in this region (0.3–2.0 μm), where they determined n for films of ZnSe from measurements of reflectance and transmittance at room temperature and also at 400 °C. At room temperature, only cubic crystals were observed in the films; the hexagonal form began to appear at 100 °C becoming more prominent as the temperature increased. Both n and k increased with temperature, and the values of n at 400 °C were in good agreement with those of Marple [15]. Ahmed and Khawaja [16] determined n between 2.5 and 14 μm using a technique due to Khawaja [17], in which the transmittance at normal incidence was measured; an iteration process was then used to produce a dispersion curve and when an acceptable version of this was obtained, it yielded both n and the specimen thickness. Over this region n fell monotonically from 2.42 to 2.40, in good agreement with Thutupalli and Tomlin's results. Marple [15] measured the refractive index of a prism by the minimum-deviation method between 0.5 and 2.5 μm for material containing less than 30 ppm of impurities, the chief ones being phosphorus, arsenic, and cadmium. The optical material was grown as single-crystal boules by sublimation in an argon-filled quartz tube. Marple claimed an experimental error of ±0.002 and was able to fit his experimental data over this wavelength region with a Sellmeier-type dispersion equation:

$$n^2 = 4.0 + 1.90\lambda^2/(\lambda^2 - 0.113),$$

where λ is the wavelength in μm.

An investigation covering the visible spectrum was made by Rambauske [18] using the minimum-deviation technique and Avery's method [19], in which the reflectance ratio (R_p/R_s) is measured. Two quite different dispersion curves were produced from two specimens of ZnSe, which had been obtained from different sources. For one specimen, the dispersion curve peaked at 0.50 μm ($n = 2.72$) and then fell rapidly as the wavelength decreased. The curve due to the second specimen closely followed those by Aven *et al.* and Thutupalli and Tomlin between 0.65 and 0.45 μm, where it peaked at $n = 2.82$. At shorter wavelengths, this curve was very different from theirs in that it fell to a value of n of 2.25 at 0.40 μm, whereas theirs, after a shoulder at 0.45 μm, went on to peak at 0.30 μm. There is some

evidence that the specimens used by Rambauske were not of high purity, and the displacement of the maximum may have been caused by the presence of impurity energy levels in the energy gap. Zholkevich [20] has determined directly the absorption coefficient of ZnSe between 0.45 and 0.65 μm; the derived values of k were very small, and they have been included in Table I with the values for n due to Balkanski and Petroff [11]. Another set of results covering a narrow range (0.476–0.633 μm) in the visible spectrum, which did not include the absorption edge, was produced by Wunderlich and De Shazer [21] also using the minimum-deviation prism technique. Their values of n, which had errors of ±0.002, were very similar to those of Rambauske over the same wavelength range.

Feldman *et al.* [22] also used the minimum-deviation method to measure n at room temperature for two specimens between 0.5 and 18.0 μm. Their values of n were quoted to five decimal places, but the results for the two specimens were not identical, and it is considered by Li that ±0.0004 is a more realistic error. A set of mean values for n calculated from the three-term dispersion formulas given by Feldman *et al.* is included in Table I, the fifth figure being given in brackets.

Measurements of n and k at wavelengths in the range 20–1000 μm have been performed by Manabe *et al.* [23] and by Hattori *et al.* [24]. Manabe *et al.* measured the reflectance of polished specimens between 20 and 85 μm at an angle of incidence of 12 degrees and determined n and k by the use of the following Lorentz-oscillator equations;

$$n^2 - k^2 = \varepsilon_\infty + N(\nu_t^2 - \nu^2)/((\nu_t^2 - \nu^2)^2 + \gamma^2\nu^2)$$

$$2nk = N\gamma\nu/((\nu_t^2 - \nu^2)^2 + \gamma^2\nu^2).$$

At 300 K, the transverse-optical-phonon frequency, $\nu_t = 207\ \text{cm}^{-1}$ (48.3 μm), the longitudinal-optical-phonon frequency, $\nu_l = 246\ \text{cm}^{-1}$ (40.7 μm), $\varepsilon_\infty = 5.4$, $N = 8.94 \times 10^5\ \text{cm}^{-2}$, and $\gamma = 3.73\ \text{cm}^{-1}$. They also produced another set of results at 100 K, where the corresponding values were $211\ \text{cm}^{-1}$, $250\ \text{cm}^{-1}$, 5.4, $9.25 \times 10^4\ \text{cm}^{-2}$, and $2.11\ \text{cm}^{-1}$. Their value of n at 20 μm and at 300 K compares well with that of Feldman *et al.* [22] at 18 μm. Hattori *et al.* [24] used transmission interferometry for their measurements taken between 100 and 1000 μm and at temperatures of 2, 80, and 300 K. Specimens were grown by Bridgman's technique and ranged in thickness between 500 and 1000 μm. Again, a simple dispersion formula was used to evaluate the optical constants. Their results agreed to within a few percent with those of Manabe *et al.* in the wavelength overlap region. They found the transverse optical phonon to be at $203\ \text{cm}^{-1}$ at 300 K, $207\ \text{cm}^{-1}$ at 80 K, and $210\ \text{cm}^{-1}$ at 2 K; the extreme long-wavelength value of n was 3.00 at

300 K and 2.96 at 80 K. Sets of results read from the graphs given by both Manabe *et al.* and Hattori *et al.* are quoted in Table I.

Miles [25] has published a graph of absorption coefficient versus wave number between 300 and 900 cm^{-1} (11–33 μm). This shows structure attributable to multiphonon absorption, the main peaks being at 360, 415, 430, 570, and 610 cm^{-1} with a shoulder at 800 cm^{-1}. The derived values of k are small (between 0.02 and 1×10^{-7}) and do not exhibit the structure clearly. Nevertheless, some values have been included in Table I. Aven *et al.* [13] have also reported results for the absorption coefficient in this region (0.02–0.08 eV, 15.5–62 μm); these had peaks at 0.026, 0.0375, 0.046, 0.0525, and 0.073 eV. (47.7, 33.1, 27.0, 23.6, and 17.0 μm). Over the main peak at 47.7 μm, the values for k agree well with those of Manabe *et al.*; other values of k, covering the regions of 30–40 μm and 50–60 μm are given in Table I.

At very low frequencies (20 Hz–1 mHz) Strzalkowski *et al.* [26] have measured the dielectric constant ε of ZnSe by the capacitance method. At 296 K, ε was equal to 9.25; that is, $n = 3.10$; ε varied linearly with temperature and, when extrapolated to 0 K, $\varepsilon_o = 8.80 \pm 0.04$; that is, $n_o = 2.97 \pm 0.02$. ε, and therefore n, were independent of wavelength out to 300 m.

Thompson *et al.* [27] measured n as a function of temperature at two discrete wavelengths, 3.8 and 10.8 μm, making use of the minimum-deviation method; it is possible to read values from their graphs to three decimal places. At 300 K and 3.8 μm, $n = 2.435$, whereas at 10.8 μm $n = 2.405$, both values being in very good agreement with those of Feldman *et al.* In each case, n fell by 0.010 when the temperature was reduced to 75 K, giving a temperature coefficient of 1.9×10^{-5}/°C. Another investigation of the effect of temperature was carried out by Tubota *et al.* [28], who studied the variation of the position of the absorption edge over the range 295–496 K. The energy gap was found to change from 2.59 eV (0.479 μm) at 293 K to 2.47 eV at 398 K and then to 2.38 eV at 496 K.

Excitons in ZnSe

At low temperatures (5 K), the presence of excitons has been detected in ZnSe crystals. These are electron-hole pairs that occupy energy levels inside the fundamental energy gap just below the conduction band; some excitons are free, and others are bound to impurity atoms. Spectroscopically, they may be represented by a simple hydrogenlike energy level series. Absorption lines are observed at energies just below the main band due to the breakup of the excitons by photons of the correct energy. This dissociation may also be brought about by thermal energy, and so it is more difficult to observe excitons at higher temperatures. An account of the properties of excitons has been given by Thomas and Timofiev [29]. Hite *et al.* [30] also found evidence for the presence of

excitons in ZnSe even though the absorption spectrum they observed was dominated by the defects in their crystals. Another group that observed the presence of excitons in ZnSe for temperatures below 60 K was Tokura *et al.* [31], who used attenuated total reflection to study the coupling of photons to excitons at the semiconductor surface. Jiang *et al.* [32] found evidence for the presence of excitons in ZnSe, bound to deep impurity levels or defects.

Irtran 4

Commercial synthetic zinc selenide, produced by hot sintering of the polycrystalline material and known as Irtran 4, has been investigated by McCarthy [33] between 2 and 50 μm using measurements of reflectance and transmittance. He produced curves of reflectance and transmittance versus wavelength but, unfortunately, did not evaluate n and k. Another study of Irtran 4 was made by Hilton and Jones [34] using a prism minimum-deviation technique to measure n between 3 and 13 μm and at temperatures of 198 and 295 K. Both values of n were presented graphically, and those for 198 K were lower by approximately 0.005 over the whole of the wavelength range covered. The temperature coefficient of n at 5 μm was found to be $2.0 \times 10^{-5}\,\mathrm{K}^{-1}$. Hadni *et al.* [35] measured the reflectance and transmittance of a thin plate of Irtran 4 and also of films of ZnSe on quartz at 290 K and at liquid-nitrogen temperature. They found that their results could be explained by postulating a single Lorentzian-type oscillator with ν_t equal to $204\,\mathrm{cm}^{-1}$ (49.0 μm) and ν_l, the longitudinal-optical-phonon frequency, equal to $254\,\mathrm{cm}^{-1}$ (39.4 μm) at 300 K. Their values for n and k were considerably smaller than those obtained by Manabe *et al.* for bulk material possibly because of the structural properties of their films. Their value of n extrapolated to very long wavelengths was 3.10 at 290 K.

There is some evidence that n for Irtran 4 may be sample dependent; nevertheless, results due to Hilton and Jones and to Hadni *et al.* are included in Table I.

Optical Properties of Zinc Telluride

The n and k data selected in this critique are listed in Table II and graphed in Fig. 2. Many of the authors who investigated zinc sellenide have also extended their work to cover the closely related material zinc telluride.

At wavelengths in the X-ray region, n and k may again be calculated by the method of Henke [4] described earlier. For ZnTe,

$$n = 1 - 7.88\lambda^2(f_{1zn} + f_{1te}),$$

where the wavelength λ is in μm. As with ZnSe, the values of n in this

region are very close to unity, and peaks in k are obtained at 0.0012 μm (the $L_{II,III}$ transition point in Zn) and 0.0021 μm (the $M_{IV,V}$ transition point in Te).

In direct measurements of the absorption coefficient, Cardona and Haensel [8] found a doublet of absorption lines for ZnTe at 89.4 and 93.0 eV (0.0133 and 0.0139 μm) corresponding to the M-transition in Zn. However, no peak for Te was discovered right up to a wavelength of 0.3 μm. Values of k for ZnTe between 0.008 and 0.033 μm, derived from α, are presented in Table II; n is assumed to be close to unity in this spectral region.

At wavelengths between 0.05 and 1.0 μm, Cardona and Greenaway [36] measured the reflectance of cleaved single-crystal ZnTe. In the region of 0.10 μm, the reflectance spectrum exhibited a number of structures that could be assigned to various electron transitions from the d-band to the conduction band in zinc (0.071 and 0.153 μm). The temperature coefficient of reflectance was approximately 6×10^{-4}/°C at all the wavelengths investigated. Cardona himself [37] measured the normal-incidence reflectance up to 20 eV at 300 and 77 K. He then calculated ε_1, ε_2, n, and k by K–K analysis and determined the dielectric constant at infinite wavelength using Penn's model [38]. His values for n and k are included in Table II.

Cardona [12] has also reported measurements of the reflectance of ZnTe at room temperature in the ultraviolet spectrum between 0.06 and 0.59 μm where 12 peaks were observed between 2.35 and 14.6 eV, all of which were accounted for in terms of electron transitions within the Brillouin zone. Freeout [6] used synchrotron radiation to measure the reflectance of cleaved ZnTe at wavelengths in the range 0.04–2.0 μm, analyzing the results by the K–K technique. He was able to correlate the structures in the reflectance spectrum with excitations of the core electrons.

Gauthe [39] studied the energy losses in 30 keV electrons on transmission through thin evaporated films of ZnTe. He found that the loss spectra were significantly different from a simple superposition of the loss spectra due to the component elements, the main loss peaks being at 4.6 and 16.3 eV and the plasmon energy at 14 eV. Tomoda and Mannami [40] also plotted the energy-loss spectrum of thin ZnTe films, which had been deposited on cubic rock salt, thus giving the zinc-blende lattice, and then dissolving away the substrate; using 40 keV electrons, they found a series of peaks ranging from 2.5–15.3 eV and also determined the plasmon energy as 12.3 eV. Walter *et al.* [41] measured the reflectance of ZnTe specimens cleaved in air along the (110) plane and subsequently maintained in a cryostat at low pressure. Taking into account the spin–orbit interactions, they were also able to make calculations of the reflectance from the band structure and claimed good agreement between the two sets of values.

Near the fundamental energy gap, the results from various studies are

again inconsistent. Loh and Newman [42] measured the transmittance of crystals of ZnTe near the fundamental edge and deduced the absorption coefficient, which was then plotted against wavelength. It was found that the absorption edge shifted upwards by about 0.1 eV as the temperature was reduced from 300 to 77 K. By measuring the absorption coefficient of hand-polished specimens of different thicknesses, it was possible to obtain estimates for the separate bulk and surface absorptions. Brown and Brodie [43] measured the reflectance and absorption spectra of amorphous ZnTe deposited on both glass and sapphire substratres; these showed only one broad maximum centered at 4.4 eV, which was associated with electron transitions near the center of the Brillouin zone in the [111] direction, that is, L direction. Their values of k between 0.35 and 0.61 μm are in reasonable agreement with those of Cardona [12] over the same spectral range.

The visible and near-infrared region has been well covered in a number of publications. Sliker and Jost [44] confirmed Cardona's results [37] and also gave tabulated values of n between 0.5 and 1.5 μm at 300 K. They used a single-crystal prism of undoped ZnTe cut from a boule grown by sublimation of high-purity zinc and tellurium; one face was polished using 0.3 μm alumina but because the material was cubic in structure, no attempt was made to align it crystallographically when making minimum-deviation measurements. Shiozawa *et al.* [45], also using the method of minimum deviation, have reported results in this same region (0.57–1.5 μm) for synthetic ZnTe. Aten *et al.* [46] used this particular experimental technique to produce a smooth curve of n versus photon energy at 300 K; at this temperature they measured the indirect energy gap as 2.164 eV. However, it is difficult to make accurate readings from the graphs they give, and their results have not been included. Working with thin films, Marple [15] used very pure ZnTe (containing less than 30 ppm of impurities) at wavelengths up to 2.0 μm and claimed an accuracy of ±0.003 in n from his minimum-deviation technique. He fitted his results into the following Sellmeier-type formula:

$$n^2 = 4.27 + 3.61/(\lambda^2 - 0.142).$$

Jensen and Torabi [47] derived a theoretical expression for the real part of the refractive index near the fundamental band edge and claimed that it gave a good fit with Marple's results. In addition, Horikoshi *et al.* [1] have reported values of n between 1.6 and 2.3 eV and at temperatures of 97 and 300 K, these being determined from their spectrophotometric measurements of transmittance. There is good agreement between this set of results and those of Marple, Shiozaka *et al.*, and Sliker and Jost. Horikoshi *et al.* also presented a graph of absorption coefficient versus energy

between 0.1 and 0.6 eV (2.0–12.0 μm) from which values of k may be calculated; k is very small (<0.01) over this range. In Table II, the values of n from Sliker and Jost and from Jensen and Torabi are presented for 300 K; Horikoshi *et al.*'s values of k between 2 and 12 μm are also included, as well as those of Zholkevich [20] between 0.5 and 0.7 μm.

Miloslavskii *et al.* [48] measured the transmittance of thin films of ZnTe and used the K–K method of analysis to calculate the phase change on transmission and hence to determine n and k. They produced a graph of n and k versus wave number between 10,000 and 22,500 cm^{-1} (0.44 and 1.0 μm), a peak in n being found at 0.526 μm. Chu *et al.* [49] also worked with films of ZnTe deposited on glass, ceramic, and tungsten, substrates at temperatures of 500–600 °C. They present a graph of the absorption coefficient squared versus energy between 2.20 and 2.28 eV for ZnTe on polished glass, and this was linear for energies just above the band gap. When extrapolated, the line intersected the energy axis at 2.25 eV, the optical band gap. Thutupalli and Tomlin's work [14] on thin films deposited at room temperature and between the wavelengths of 0.3 and 2.0 μm produced values of n that were in general smaller than those quoted in Table II, but when deposition took place at a substrate temperature of 325 °C, the values of n became very similar to those for the bulk material. A set of data in the near-infrared has also been published by Masso and Turner [50]. Where overlap of wavelength occurs, these data are in good agreement with those of Thutupalli and Tomlin for room-temperature deposition. For this wavelength region, Table II gives values of n due to Jensen and Torabi and also a set of values due to Masso and Turner, read off from the graph given by Li.

At long wavelengths (20–85 μm), Manabe *et al.* [23] again used the Lorentz-oscillator dispersion relationship quoted earlier to calculate n and k from their reflectance measurements on ZnTe. At 300 K, $\nu_t = 177\ cm^{-1}$, $\nu_l = 206\ cm^{-1}$, $\varepsilon_\infty = 6.7$, $N = 7.26 \times 10^4\ cm^{-2}$, and $\gamma = 3.01\ cm^{-1}$. At 100 K, the corresponding values were $180\ cm^{-1}$, $210\ cm^{-1}$, 6.7, $7.52 \times 10^4\ cm^{-2}$, and $2.34\ cm^{-1}$. Hadni *et al.* [35] measured the reflectance and transmittance of a pellet of ZnTe in the far infrared, explaining their results in terms of a single Lorentz-oscillator; this also produced values of $177\ cm^{-1}$ for ν_t and $205\ cm^{-1}$ for ν_l at 300 K. Hattori *et al.* [24] used their transmission interference technique to make measurements of n and k in the range 100–1000 μm and at temperatures of 300, 80, and 2 K; they were able to express their results in the form of a simple Sellmeier dispersion formula. Extrapolated to infinitely long wavelengths, the value of n became 3.15 at 300 K, 3.11 at 80 K, and 3.10 at 2 K. The corresponding values of the transverse-optical-phonon frequency were 180, 190, and $192\ cm^{-1}$, respectively. Nahory and Fan [51] presented graphs of the absorption coefficient of single crystals of ZnTe at wavelengths between the visible and 50 μm and at temperatures of 295 and 10 K. Most of the room-temperature

absorption was due to free holes, but there was some wavelength-related structure caused by lattice vibrations. Their values of k at room temperature are used in Table II, which also includes the optical constants due to Manabe *et al.*, Hadni *et al.*, and Hattori *et al.*

Excitons in ZnTe

Kurik and Manzhara [52] studied the exciton reflectance spectra of ZnTe single crystals, also noting the effects produced by the crystal defects. Pevtsov and Sel'kin [53] obtained the spectrum of excitons at 2 K by measurements of the reflectance and the phase change on reflection in both the s and p states of polarization. Their results appeared to fit well with the theoretical model of Thomas and Hopfield [54].

Aluminum Oxide (Al_2O_3)

FRANÇOIS GERVAIS
Centre de Recherches sur la Physique des Hautes Températures
Centre National de la Recherche Scientifique
45071 Orléans, France

Aluminum oxide crystallizes in the corundum (α-Al_2O_3) rhombohedral structure. It is also known as sapphire. The system is uniaxial and optical properties measured on a single crystal are therefore anisotropic. The structure of the oxygen sublattice is close-packed. As a result, the anisotropy of the refractive index in the visible region, mainly related to the anisotropy of the oxygen polarizability is small (less than 2%). In the millimeter-wave range, the anisotropy reaches 10%. The optical constants selected are listed in Table I and plotted in Fig. 1.

A study including original measurements and a compilation of previous data, which extends over a wide energy range, from 6 eV up to 1.6×10^3 eV, has been performed at the Deutsches Elektronen-synchrotron DESY [1]. The compilation concerns Refs. [2–5]. Although measurements have been performed on evaporated amorphous Al_2O_3 such that information related to anisotropy is lost, they are of practical interest. Results agree well with previous measurements at low energies but extend over a much wider energy range. Optical absorption measurements performed on single-crystal samples, but restricted to the 1–6 eV range, were reported in Refs. [6, 7]. Some anisotropy of the spectra is displayed in [6]. However, these spectra are of little practical interest, since it is difficult to extract n and k from the UV edge by Kramers–Kronig analysis in a too-narrow energy range where there is strong dispersion. Results of [1] are given in Table I.

The indexes of refraction of a synthetic sapphire prism measured over its entire range of transmission (0.2–6 μm) is reported in Ref. [8]. The optic axis of the prism was oriented parallel to the base and perpendicular to the apex, so that measurements refer to the ordinary ray (electric field perpendicular to the c axis of the corundum structure). Results are listed in Table I.

Measurements in the infrared were reported in the literature at the beginning of this century. However, the quantitative exploitation of

infrared reflectivity spectra started with the availability of computers in the 1960s. The most complete set of measurements in the infrared complemented by data processing was performed by Barker [9]. Several single crystals from different origins were compared. Measurements were performed with a prism spectrometer. Barker emphasized the large differences that may appear from one sample to another in specific spectral regions. The forbidden modes disappear after etching of the surface. Measurements analyzed in Refs. [11] and [12] were performed on a single crystal previously annealed at 1775 K, thus above 3/4 of the temperature of the melting point, to regenerate the surface partially altered by the polishing. The spectra then consist of normal vibrational modes only, and no extra modes are visible.

Surprisingly, the literature is short of data concerning n and k in alumina ceramics. A study of this type was published only recently [12], performed with a grating spectrometer. The hot-pressed alumina sample was as-fired. The spectrum mainly resembles that for the ordinary ray of a single crystal but of course also contains features related to the extraordinary ray. Again, the authors emphasize the influence of polishing on the appearance of forbidden modes. The authors seem to have been surprised by the existence of a weak band at approximately $500\,\mathrm{cm}^{-1}$. This is simply the signature of the presence of the longitudinal optical mode at $514\,\mathrm{cm}^{-1}$ for the electric field polarized parallel to the c axis (extraordinary ray) in the vicinity of the LO mode at $482\,\mathrm{cm}^{-1}$ for the ordinary ray. In randomly oriented materials, a reflection band necessarily develops between the two values that cancel the real part of the dielectric response. In other words, there is necessarily a maximum between two minima of the dielectric response. In Ref. [12], the optical constants are calculated by Kramers–Kronig relations.

In single crystals, the dielectric function can be modeled. As soon as a dielectric function model fits the infrared reflectivity, one may deduce the optical constants more accurately than with a Kramers–Kronig analysis. The absorption coefficient is found to be extremely high. The penetration depth of the infrared radiation is found currently smaller than 1 μm at a peak corresponding to a normal vibrational mode. As a result, the infrared beam in these spectral regions probes the surface of the sample rather than the bulk. The result is then very sensitive to the alterations of the crystal surface, as shown by various authors. Conversely, in the vicinity of vibrational-mode frequencies, the results reflect bulk properties on etched surfaces or annealed crystals. This is also true far from normal modes, because then the penetration depth of the infrared beam is much larger. Disorder or alteration of the sample surface increases mode damping and therefore lowers the reflectivity level. The higher the reflectivity, the better is the sample quality generally. Note that fitting the spectra minimizes the spurious effects of the surface (by comparison with a Kramers–Kronig

analysis) because the damping is averaged over a wide spectral range (with larger penetration depth on average) in the former case, instead of being determined too near the mode frequency where disorder may alter the result.

Barker [9] fitted his spectra with the dielectric-function model

$$\varepsilon = \varepsilon_\infty + \sum_j \Delta\varepsilon_j \frac{\Omega_{j\mathrm{TO}}^2}{\Omega_{j\mathrm{TO}}^2 - \omega^2 + i\gamma_{j\mathrm{TO}}\omega}. \tag{1}$$

Here ε stands for the dielectric function, ε_∞ is the high-frequency dielectric constant, $\Delta\varepsilon$, Ω, and γ are the oscillator strength, the frequency, and the damping of the jth TO (transverse optic) mode, respectively. Results have been used to calculate the n and k data given in Table I.

A factorization over poles and zeros of the dielectric response in the form

$$\varepsilon = \varepsilon_\infty \prod_j \frac{\Omega_{j\mathrm{LO}}^2 - \omega^2 + i_{j\mathrm{LO}}\omega}{\Omega_{j\mathrm{TO}}^2 - \omega^2 + i\gamma_{j\mathrm{TO}}\omega} \tag{2}$$

was preferred in Refs. [10] and [11]. Here the index LO refers to longitudinal optic modes. The reason invoked by the authors is that in highly polar systems where the coulombic field splits the polar modes into transverse and longitudinal components (one being possibly twice more energetic than the other), phonons have very different decays, and mode damping is possibly very different. Conversely, identical dampings are implicitly assumed for the TO and LO components by the model in Eq. 1. Results deduced from the fit to the reflectivity data with the dielectric-function model in Eq. 2 are compared with those of Barker [9] in Table I. Data are given for the electric field of infrared radiation polarized perpendicular (ordinary ray) and parallel (extraordinary ray) to the crystal c axis. The overall agreement is good. Discrepancies appear in the regions of poor fitting in Eq. 1 and mainly near highly polar TO modes, where surface effects limit the penetration depth of the infrared radiation, thus giving less-sharp peaks for n and k. Note that this fitting procedure yields better agreement to the data near the normal vibrational modes, but results far from the resonances are less reliable than those calculated with Eq. (1).

Also included in Table I are the data given in [12] for a polycrystalline sample of hot-pressed 99.9% alumina. These data have been deduced by the author of the measurements via a Kramers–Kronig analysis of his reflectivity data.

Aluminum Oxynitride (ALON) Spinel

WILLIAM J. TROPF and MICHAEL E. THOMAS
Applied Physics Laboratory
The Johns Hopkins University
Laurel, Maryland

Aluminum oxynitride, or ALON, is a crystal made of various amounts of aluminum oxide and aluminum nitride, with the aluminum-nitride content between 27 and 40 mole-percent. The resulting material, a nitrogen-stabilized cubic aluminum oxide, is face-centered cubic with spinel structure (see "Magnesium Aluminum Spinel," this volume). The lattice parameter of ALON varies from 7.938 (30 mole-percent AlN) to 7.951 (38 mole-percent AlN) [1]. Of particular interest is the composition of ≈35.7 mole-percent, which is equivalent to the composition $5AlN9Al_2O_3$ or $Al_{23}O_{27}N_5$. This composition has a unit cell with lattice parameter of 0.7948 nm [1]. Theoretical density of this composition is 3.71 g/cm^3 and melting point is 2323 K [1] to 2438±15 K [2].

Aluminum oxynitride is termed a nonstoichiometric spinel because some cation sites are occupied by vacancies. McCauley [3] proposed a formula of the form

$$Al_{(64+X)/3}\square_{(8-X)/3}O_{32-X}N_X \qquad 0 \leqslant x \leqslant 8, \tag{1}$$

where $x = 0$ corresponds to γ-alumina, and $x = 8$ is the unstable stoichiometric oxynitride Al_3O_3N. The symbol □ denotes cation vacancies. Since ALON exists over the range 27–40 mole-percent AlN, values of x for ALON range from approximately 3.5 to 5.8. When the composition is 35.7 mole-percent AlN ($x = 5$), there is one cation vacancy per unit cell. Neutron-diffraction studies (see [2]) confirm that oxygen and nitrogen occupy the anion sites of the spinel lattice and that aluminum cations occupy both the octahedral and tetrahedral sites of the spinel ($Fd3m$) structure. Corbin [2] implies that the vacancies occur at the octahedral cation sites.

ALON can be produced by a variety of methods, including reaction sintering of alumina and aluminum nitride, simultaneous reduction and nitridation of alumina, combustionlike reaction of aluminum metal with

oxygen and nitrogen, and reaction of gases [2]. Commercial optical ALON is made by reacting the raw materials, pressing into near-finished shape, and firing at high temperature to produce a fully dense, transparent ceramic [4]. The resulting high-temperature, high-strength ceramic is used for windows and optical elements where hardness and resistance to harsh environments is important. Property data for ALON are given in the literature [4–7].

ALON is transparent at 0.230 to 5.0 μm. The band gaps of the constituent materials, alumina and aluminum nitride, are 9.9 and 6.0 eV, respectively [8]. From this information we surmise a band gap of 6–7 eV.

Index-of-refraction data for ALON are very sparse. Hartnett and Gentilman give a measured value of 1.793 at 0.589 μm and an estimated value of 1.66 at 4 μm based on reflection loss [4]. Corbin [2] and Hartnett *et al.* [9] give an index of refraction from 1.770 (also see [1]) to 1.785 in the visible (0.55 μm) as the composition increases from 30% to 37.5% AlN.

Precision room-temperature index-of-refraction measurements have also been made by Scheller [10] using a prism supplied by Raytheon. These values were used to construct the following Sellmeier formula:

$$n^2 - 1 = \frac{20.32 \times 10^9}{(97{,}500)^2 - \nu^2} + \frac{1.287 \times 10^6}{(530)^2 - \nu^2}, \tag{2}$$

where ν is the frequency in wave numbers. This formula is applicable to bulk polycrystalline ALON (37.5% AlN) in the range of 0.4–2.3 μm and duplicates measurements to within ±0.0002.

The dominant loss mechanism in the visible and near-IR transparent region of polycrystalline ALON is scatter. Bulk scatter in polycrystalline ALON is low and decreases with increasing wavelength [4, 5].

Absorption at the IR edge of transparency is dominated by multiphonon absorption. A model of multiphonon absorption for ALON has been developed and validated with experimental data over a wide temperature range [11]. ALON exhibits a two-phonon structure in the 1700–1950 cm^{-1} region that is not adequately represented by this multiphonon model. The fundamental (one-phonon) lattice vibrations occur in the 350–970 cm^{-1} spectral region.

Table I gives the transverse and longitudinal optical frequencies of ALON [12] as determined by reflectance measurements. The transverse optical frequencies are the mode locations, and the maximum longitudinal frequency is an important parameter in the multiphonon model [11], since it designates the maximum phonon frequency.

At frequencies below the lowest fundamental optical mode, absorption decreases, and the material becomes transparent. The magnitude of absorption is thought to be a combination of contributions from both the

tail of the fundamental lattice vibrations and various multiphonon difference bands. The index of refraction now also includes the effect of lattice vibrations.

The low-frequency real index of refraction (dielectric constant) of ALON is given as 2.93 by McCauley and Corbin [1] for a composition of 30% AlN and as 3.06 by Stead and Simonis [13] for ALON with 37.5% AlN. Temperature dependence of the low-frequency index of refraction is given by Ho [14] as 2.2×10^{-4}/K (average, 23–300 °C), 2.7×10^{-4}/K (average, 23–1000 °C), and 3.0×10^{-4}/K (average, 23–1200 °C). Stead and Simonis [13] give values for the imaginary index of refraction (k) in the 7–16 cm^{-1} region. Estimates made from the red wing of the fundamental modes (Table I) are three to four times greater than the experimental imaginary index-of-refraction value determined by Stead and Simonis [13] at 10 and 15 cm^{-1}. Corbin [2] also gives absorption coefficient data in the 5–40 cm^{-1} range for ALON of an unreported composition. These values agree well with model predictions of k, but tend to have lower values at low frequency.

The high-temperature electrical conductivity of ALON was measured by Kim and Richards [15] and found to be typical of oxides. They found a correlation between the number of vacancies (see Eq. [1]) and conductivity and interpret the conductivity as ionic.

Table II was constructed from measurements reported in the literature as well as model predictions. Real-index data (n) in the visible and near IR are taken from the measurements by Scheller [10]. Lattice-vibration-model results [12] are used to calculate real-index data from 0–10,000 cm^{-1} and imaginary-index data from 5–3300 cm^{-1}. Laser-calorimetry results for k at 2.9 and 3.9 μm by Detrio and Greason [16] give measurements of the imaginary part of the index of refraction, based on thin samples with the lowest absorption coefficients. Note that the value at 3.9 μm agrees well with the multiphonon-absorption-model prediction [11, 12]. The measured value at 2.9 μm is much higher than the multiphonon model value because of the presence of an OH^- impurity vibrational band.

Measurements of Stead and Simonis [13] are used to represent the low-frequency characteristics of ALON (37.5% AlN). In this region, one-phonon model predictions [12] of k are several times the measured values [13], probably because a few wide fundamental modes are used to represent many narrower modes, and the broadness of these modes gives excessive low-frequency-wing absorption. Values of k for ALON of unknown composition are also given [2]. Low-frequency index predictions are virtually the same as measurements [13]. At very low frequency, ALON exhibits considerable free-carrier absorption that increases rapidly with temperature [9]. Extrapolation of this low-frequency absorption (in the region dominated by free-carrier effects) to 100 GHz (3 cm^{-1}) gives a value for k of 3×10^{-4} for ALON (30 mole-percent AlN) [9], consistent

with the data given in Table II. ALON with 30 mole-percent AlN has a low-frequency index of refraction of 2.9 [9].

Index measurements by Scheller [10] are accurate to ± 0.00001. Calculated index data are probably accurate to ± 0.01 for n (outside the range of measured values) and $\pm 5\%$ for k down to 350 cm^{-1}. Calculated values of k below 350 cm^{-1} are too high, ultimately by a factor of four at low frequency. In all data, except k below 350 cm^{-1}, the uncertainty in the values is probably in the least significant digit reported in Table II.

Figure 1 shows a composite of the complex index of refraction based on the data of Table II.

Table III gives temperature dependence for the real part of the index of refraction. Our measurements of dn/dT in the visible and those of Ho [14] at low frequency are given.

Temperature-dependent absorption computed from optical models of ALON [12] have been used to estimate total hemispherical emissivity of pure, transparent ALON over the temperature range 200–1000 K, where the models are expected to give the best results and defect absorption is believed to be insignificant. These results were obtained by estimating complex refractive index at a given temperature, calculating directional emittance for a specific slab thickness, integrating over angle, and convolving the resulting spectral hemispherical emittances with the Planck function.

Table IV gives the resulting total hemispherical emittance for semi-infinite slabs as a function of slab thickness. Since total hemispherical emissivity is an important function for radiation-relief calculations and may be needed to correct property measurements such as thermal conductivity, we have included this calculated result.

NOTES ADDED IN PROOF

The electronic structure and bang gap of ALON was recently measured by French [17]. The first UV absorption peak occurs at 7.3 eV and bandgap is approximately 6.2 eV.

Details of the measurement of dn/dT at 0.6328 μm in Table III are given in [18]. Spectral and directional scatter measurement of commercial ALON are given in [19].

6	920	0.03	0.050	969	[12]
	Total = 6.24				

[a]The transverse optical frequency (ν_j) is the location of the mode. The strength ($\Delta\epsilon_j$) is the contribution of the mode to the dielectric constant. The normalized width (γ_j) is the mode width divided by the mode frequency. The complex dielectric constant (ϵ) is then modeled as a function of frequency (ν) by:

$$\epsilon(\nu) = \epsilon_\infty + \sum_j \frac{\Delta\epsilon_j \, \nu_j^2}{\nu_j^2 - \nu^2 + i\gamma_j \nu_j \nu} ,$$

where the ϵ_∞ term (= 3.1375) represents the electronic contributions to the dielectric constant (plus one). This model has a static dielectric constant of 9.38.

The barium titanate crystal is ferroelectric at room temperature. The crystal structure is perovskite, cubic above the Curie temperature, and tetragonal below the Curie temperature. At room temperature, the *c* axis is longer than the *a* axis by 1% [1]. Practically all the barium titanate samples described in the literature were fabricated by either the flux-grown or the melt-grown method. The process of growing large single crystals of barium titanate by the top-seeded melt growth was developed by a group headed by A. Linz at MIT [2] and later transferred to Sanders Associates [3], which is presently a major commercial supplier of this crystal. The Curie temperature of melt-grown barium titanate is about 133 °C, while that of flux-grown is 120 °C. The lower Curie temperature of flux-grown barium titanate is believed to be a result of the higher impurity content, which also affects the optical constants. Recently, there has been increased interest in barium titanate, mainly due to its photorefractive properties and other associated effects and applications, such as phase conjugation, volume holography for optical storage, two-beam coupling, and optical computing.

The UV data in Table II are the result of Kramers–Kronig (K–K) analysis of reflectivity measurement on unpoled multiple-domain samples. They represent a certain weighted average of the optical constants for the ordinary (o) and extraordinary (e) rays. The o-ray is expected to dominate because it has an entire plane of polarization, whereas the e-ray has only one direction of polarization [4]. We read the n and k values from the graphs of Bäuerle *et al.* [5], who measured the reflectivity from 10–32 eV at room temperature, and did a K–K analysis of a combination of their own reflectivity data and Cardona's [6] 2–22 eV, room-temperature data. At 2.94 eV, these graphs give $n = 2.67$, $k = 0.05$, whereas Table II lists

$n_o = 2.644$, $n_e = 2.541$ from minimum deviation and $k_o = 5.84 \times 10^{-6}$, $k_e = 6.51 \times 10^{-6}$ from absorption measurements. There is significant disagreement in the k values. The reflectivity measurement of Bäuerle *et al.* [5] involved the polarized synchrotron radiation from the DORIS storage ring at Hamburg together with a modified special UHV version of the McPherson Model 225.3 monochromator with a resolution of 0.03 Å. The sample was a polished single crystal with (100) faces in the cubic phase. Cardona [6] used unpolarized light from various arc lamps, and a 1-m McPherson monochromator. The unpoled sample was polished, etched, and had random orientation for the ferroelectric domains.

For the visible region, we tabulate the room-temperature index of refraction data from Wemple *et al.* [7], covering the range 0.42–0.68 μm. Their sample was melt-grown. The method of measurement was minimum deviation. The sample was poled to a single domain, then cut with a string saw to minimize surface damage and polished with 6 and 3 μm diamond paste on a flat tin lap. The data can be represented by the following single-oscillator Sellmeier equations:

$$n_o^2 = 1 + \frac{4.219}{1 - (0.2231/\lambda)^2}$$
$$n_e^2 = 1 + \frac{4.064}{1 - (0.2109/\lambda)^2}, \tag{1}$$

where λ is wavelength in μm. Discrepancy between Eq. 1 and the data is within 0.003 for wavelengths shorter than 0.45 μm, higher for shorter wavelengths. We read the data from the graphs in Fig. 4 of Ref. [7]. The measurements by Deshpande *et al.* [8, 9] at the wavelength of the sodium D line using two different methods agree well with the data of Wemple *et al.* [7]. The first method [8] is a refinement of Duc de Chaulnes' method of image displacement. The second method [9] uses the phenomenon of polarization by reflection, and the results are $n_o = 2.428 \pm 0.002$, $n_e = 2.371 \pm 0.0045$. According to Deshpande *et al.* [8, 9], these methods can achieve accuracy better than or comparable to that of minimum deviation in the case of ferroelectric barium titanate. As for flux-grown samples, the data of Johnston [10] agree well with those of Wemple *et al.* [7] for the o-ray, although the e-ray data are slightly larger. The explanation is in the difference in polarization of the flux-grown and melt-grown samples. Johnston [10] used the method of minimum deviation and analyzed his data with a two-oscillator Sellmeier equation.

The extinction coefficient k in the UV–VIS range was calculated using

the absorption coefficient data from DiDomenico and Wemple [11] and Schunemann *et al.* [12]. Both their samples were melt-grown. Schunemann *et al.* [12] prepared a particularly pure sample and made absorption measurements between 0.4 and 0.85 μm. Temperature was not mentioned, but must be room temperature. DiDomenico and Wemple [11] made their measurements at 33 °C, between 2.95 and 3.27 eV (0.38–0.42 μm), near the absorption edge. Their absorption coefficient data exhibit an exponential Urbach tail, and there is a large difference between the o- and e-rays. At about 0.4 μm, where measurements of DiDomenico and Wemple [11] and Schunemann *et al.* [12] overlap, their data agree to within 50%. The absorption coefficient was found to be very sensitive to small amounts of impurities [13]. Klein and Schwartz [14] measured the absorption coefficient between 0.44 and 0.64 μm of four samples grown by Sanders Associates [3] and obtained results from 0.16 to 2.2 cm^{-1} at 0.5 μm. Flux-grown barium titanate was found to have higher absorption coefficients than those of melt-grown [11, 15].

In the near-IR region, the index of refraction between 0.85 and 2 μm was calculated using Eq. 1. Equation 1 is probably valid in this region because the value of n_o at 2 μm calculated from this equation agrees with the reflectivity data of Spitzer *et al.* [16]. Furthermore, the absorption in this region is very low according to Schunemann [17] and Hilsum [18]. Schunemann [17] measured the absorption coefficient between 0.85 and 3 μm on the same very pure sample [12] using unpolarized light. The absorption coefficient reaches a minimum at about 2 μm where the extinction coefficient k is about 10^{-7}. Hilsum [18] reported transmission and absorption data between 1 and 12 μm, and the minimum absorption also occurs around 2 μm with k about 10^{-5}. Hilsum's [18] sample is a yellowish plate several millimeters square and 0.1 mm thick. Temperature was not mentioned. A plot of α versus wavelength from 7 to 12 μm has been used to determine k as listed in Table II. No crystal orientation was specified, so we assume $k_o(\perp)$.

The index of refraction below the band gap for many covalent and ionic materials has been discussed by Wemple and DiDomenico [19], who developed a model equation of the form

$$n^2 = \frac{1 + E_d E_o}{E_o^2 - (\hbar\omega)^2}$$

to fit many materials. For $BaTiO_3$, $E_d = 24.0$ eV and $E_o = 5.63$ eV. Although this does not take into account the birefringence, it gives values closely approaching $n_o(\perp)$, so we have included these values (three significant figures) in Table II.

For the region between 10 and 1000 μm, Servoin *et al.* [20] measured the reflectivity with a Fourier-transform scanning interferometer, on a small, natural, single domain in the surface of a crystal. They fitted their data with the four-parameter factorized form of the dielectric function

$$\varepsilon = \varepsilon' \pm i\varepsilon'' = \varepsilon_\infty \prod_j \frac{\Omega_{j\mathrm{LO}}^2 - \omega^2 \mp i\gamma_{j\mathrm{LO}}\omega}{\Omega_{j\mathrm{TO}}^2 - \omega^2 \mp i\gamma_{j\mathrm{TO}}\omega}, \tag{2}$$

where ω is the frequency, Ω and γ are the mode frequency and damping constant, respectively, and ε_∞ is the high-frequency dielectric constant. Preliminary values of the mode frequencies and damping constants were obtained from Raman spectra and then fine-tuned to fit the reflectivity data. The fit is very good. In Table II, the n and k values from 2 to 1000 μm were calculated using Eq. 2 and the values of mode frequencies and damping constants given by Servoin *et al.* [20]. These parameters are listed in Table I. To fit the reflectivity data of Servoin *et al.* [20], we chose 5.3 to be the high-frequency dielectric constant for the o-ray, and 5.1 for the e-ray. We have extended the use of Eq. 2 to obtain the n and k values in the 2–10 μm region. Results from Eq. 2 in this region agree with the data of Spitzer *et al.* [16] who measured the o-ray reflectivity at room temperature from 5000 to 70 cm^{-1} using a double-pass prism spectrometer between 5000 and 333 cm^{-1} and a single-pass grating monochromator below 333 cm^{-1}. The reflectivity data of Servoin *et al.* [20] agree with those of Spitzer *et al.* [16] to within 2–3%, and Sanjurjo *et al.* [4], except at low frequencies.

Sanjurjo *et al.* [21] fitted their room-temperature (not defined) reflectivity data for $\mathbf{E}\|c$ with a coupled-mode model, noting that real coupling (in contrast to imaginary coupling and independent oscillators) provided the best fit. They displayed graphs of $\varepsilon_1(\|)$ and $\varepsilon_2(\|)$ in a coarser grid than the calculated values of Servoin *et al.* [20], also given in Table II. We have displayed these data in a separate block at the end of Table II. Although most values of n and k are well within a factor of two of each other, it is interesting to note where large differences occur. Sanjurjo *et al.* [21] also performed a K–K analysis of their reflectivity data demonstrating a good qualitative agreement with the coupled-oscillator-model fit. They displayed only $\varepsilon_2(\|)$ in this case.

Ballantyne [22] measured the reflectivity of the o-ray only, from 4000 to 5 cm^{-1} and between 24 and 200 °C using various spectrometers, an interferometer, and a Carcinotron system, and permittivities were obtained from K–K analysis. The n values, calculated from Ballantyne's [22] permittivities, agree with those of Servoin *et al.* [20] at the ends of the spectral region: within 1% at 10 cm^{-1} and 6% at 900 cm^{-1}. The discrepancy increases to 24% at 600 cm^{-1} and 90% at 200 cm^{-1}. There is better

agreement for the k values, especially when they are larger than unity. Barker [23] measured the reflectivity between 400 and 100 cm^{-1} at 300 K and 475 K on a multiple-domain sample, and the spectra resemble closely the o-ray spectra of Servoin *et al.* [20].

It is interesting to observe that an "antiresonance" occurs at 780 cm^{-1} (12.82 μm) where $n_o = 1.01$ and $k_o = 9.18 \times 10^{-4}$ as shown in Table II. A similar antiresonance occurs at 800 cm^{-1} (12.50 μm), where $n_e = 1.03$ and $k_e = 6.18 \times 10^{-3}$. At antiresonances, an incident ray will suffer very small reflection and absorption. Antiresonance is a quantum effect occurring when two electronic levels attempt to cross each other. The integrated absorption remains constant, but the absorption is redistributed. When two phonon levels (frequencies) attempt to cross (couple), the effect also occurs. The factorized form of Eq. 2 leads to such effects. Note that the model predicts much too much absorption in the 2.5–10 μm region compared with the measurement of Hilsum [18].

In the microwave region at a wavelength of 12 mm, we have $n_o = 39$ and $k_o = 4.7$, calculated from Ballantyne's [22] permittivity data (accuracy 20%) measured with a microwave dielectrometer. As a comparison, Eq. 2 gives, at 12.5 mm, $n_o = 46$ and $k_o = 1.6$.

Turik and Shevchenko [24] measured the permittivity along the c axis in the 1×10^3 to 3×10^8 Hz frequency range using a bridge and various Q meters. They found piezoelectric resonance at 10^6–10^7 Hz. Permittivity data from other authors [25] were also presented. At 10^{10} Hz, we have $\varepsilon_{33} = 44.9$ and the loss tangent $\tan \delta = 0.24$, from which we obtain $n_e = 6.74$ and $k_e = 0.798$. At 10^4–10^5 Hz, $\varepsilon_{33} = 188$, $\tan \delta = 0.027$, $n_e = 13.7$, and $k_e = 0.187$.

Papers dealing with optical properties of powders and small particles include Ruppin [26], Mara *et al.* [27], Last [28] and Demeshina and Murzin [29].

Although we have stressed room-temperature measurements, there has been much work (both IR and Raman) through the Curie temperature at 133 °C. IR data are found in Luspin *et al.* [30]. Some of the Raman data are found in DiDomenico *et al.* [31], Vogt *et al.* [32], Pinczuk *et al.* [33], and references therein.

ACKNOWLEDGMENTS

We would like to thank the editor for valuable suggestions, D. Bäuerle for providing a larger-size graph of n and k, and P. G. Schunemann for a copy of his thesis. The assistance of C. H. Lin, L. Li, and M. Villani in the preparation of the tables is greatly appreciated.

[a] The references are given in brackets at the beginning of the tabulation of n and k and are understood to refer to all n's or all k's below it until a new reference appears. When an exponent of 10 is given, all numbers below it have the same exponent until the power of 10 changes or the next number has 10^{-1}, which is usually written as a decimal. The samples used in Refs. [7], [11] and [12] were melt-grown. Method of sample growth were not mentioned in Refs. [5] and [20]. The optical constants from Ref. [5] are for unpoled samples.

Beryllium Oxide (BeO)

DAVID F. EDWARDS and RICHARD H. WHITE
University of California
Lawrence Livermore National Laboratory
Livermore, California

The optical properties of crystalline synthetic beryllium oxide, BeO, have been reported for a very limited number of samples. The main reasons for this lack of data are probably the toxic properties of the material and the difficulty of growing large optical-quality crystals [1]. As pointed out by Peterson and Palma [2], BeO is a useful new optical material for the vacuum UV because of its high transmittance down to about 9.4 eV (1320 Å) and its apparent resistance to UV radiation damage. In their report they show only the transmittance and, unfortunately, not enough data to estimate the n and k values for the 3–10 eV region. Calculations by White, Edwards, and Rathkopf [3] predict that overlayers of BeO on metallic reflectors should significantly enhance their hardness to X-ray radiation.

Natural bromellite (BeO) and synthetically grown BeO crystals are uniaxially positive. Newkirk *et al.* [4], using the angle-of-minimum-deviation technique, have measured the ordinary and extraordinary refractive indices and their dependence on temperature from 0.430 μm to 0.690 μm.

Loh [5] has evaluated the ordinary and extraordinary infrared refractive indices and extinction coefficients for BeO from their polarized reflectance spectra. The n and k values were derived from parameters used to fit the classical oscillator dispersion formula to the reflectance spectra. The well-known formula, as used by Loh, is

$$\varepsilon(\omega) - n_\infty^2 = (\varepsilon_0 - n_\infty^2)\omega_0^2/(\omega_0^2 - \omega^2 + i\gamma\omega),$$

where ε_0 is the static dielectric constant, and n_∞^2 is the high-frequency dielectric constant. γ is a phenomenological damping term, and ω_0 is the transverse optical resonance frequency. These classical dispersion parameters are given in Table I. The n and k values were determined from the

complex dielectric constant and are included in Table II (and Fig. 1) for the infrared region 100 to 1400 cm^{-1} (100 to 7.14 μm). These calculations were extended beyond the measurement range (up to 400 cm^{-1}) to 100 cm^{-1} in order to estimate the static dielectric constant, ε_o. From the classical dispersion analysis of Loh, $\varepsilon_o(\|) = 7.65$ and $\varepsilon_o(\perp) = 6.94$. From Table II, $n(\|)^2 = 7.765$ and $n(\perp)^2 = 6.96$ at 100 cm^{-1}.

The indices of refraction between 0.440 μm and 7.0 μm have been fit to both a Herzberger-type and a modified Sellmeier-type dispersion formula. A total of 31 and 29 wavelengths were used for fitting the ordinary and extraordinary indices, respectively. The indices for wavelengths greater than 7.0 μm are from the lattice band spectra of Loh [5] and are not included in the dispersion formulas.

The Herzberger-type dispersion formula for the index is [6]

$$n = A + BL + CL^2 + D\lambda^2 + E\lambda^4,$$

where $L = 1/(\lambda^2 - 2.80 \times 10^6)$ with λ in angstroms. As explained by Herzberger [6], the 2.80×10^6 is the square of the mean asymptote for the short-wavelength abrupt increase in the index for 14 materials (BeO not included). The coefficients for the room-temperature ordinary indices, evaluated by least squares, are $A = 1.699773$, $B = 7.451288 \times 10^2$, $C = -4.331397 \times 10^{12}$, $D = -8.194535 \times 10^{-12}$, and $E = -1.659630 \times 10^{-20}$. The RMS error between the measured values and the dispersion formula calculated indices is 0.355% for the 0.440 to 7.0 μm range. The coefficients for the extraordinary indices are $A = 1.715140$, $B = 7.871215 \times 10^5$, $C = -4.782711 \times 10^{12}$, $D = -2.139439 \times 10^{-11}$, and $E = -1.390880 \times 10^{-20}$. The RMS error is 0.263%. The calculated n_o and n_e values are included in Table II.

The modified Sellmeier-type dispersion formula [7] is

$$n^2 = 1 + A/(\lambda^2 - B) + C\lambda^2/(\lambda^2 - D),$$

where the wavelength λ is in angstroms. For the 31 ordinary and 29 extraordinary data points, the coefficients are as follows. For the ordinary index of refraction, $A = 3.698124 \times 10^{-6}$, $B = -1.878147 \times 10^{-6}$, $C = 1.953730$, and $D = 1.472502 \times 10^{-6}$. The extraordinary coefficients are $A = 3.257604 \times 10^{-6}$, $B = -1.609457 \times 10^{-6}$, $C = 1.997330$, and $D = 1.548286 \times 10^{-6}$. The RMS errors are 0.228% and 0.216% for the ordinary and extraordinary indices, respectively. The Sellmeier-calculated indices are not tabulated here but the equation and coefficients are included for completeness.

Worrell [8] has determined the infrared optical constants for commer-

cially available ceramic beryllia, BeO. He evaluated n and k from a Kramers–Kronig analysis of the reflectance spectrum at near normal incidence. His results for one of the two measured samples are tabulated in Table III. The data for the second sample are not listed here but have the same general features with some variation in detail. Comparisons have been made of these ceramic data with those of Loh [5] for the crystalline BeO. The ceramic beryllia is optically isotropic compared with the uniaxial crystalline BeO. Plots of the ceramic data are not shown here but a comparison with the Loh data shows that the reststrahlen band is the same for the two materials: 1200 to 600 cm^{-1}. The maximum reflectance at the center of this band (around 800 cm^{-1}) is less than that of the crystalline BeO: approximately, 84% versus 96%. This lower reflectance is attributed to a lower density and the polycrystalline nature of the ceramic relative to the crystal. Differences in band profile are noted with the appearance of shoulder bands at approximately 1070 cm^{-1} and 710 cm^{-1} in the ceramic materials. The peak values of the index and extinction coefficient are about 10 to 13 for the crystal and about half that for the ceramic. The n and k values outside of the reststrahlen band show greater variation with the Loh data. The reason is that corrections were not applied by Worrell [8] to the Kramers–Kronig analysis to account for truncations.

Newkirk *et al.* [4] measured the ordinary and extraordinary indices at five different temperatures from -12.06 ± 0.01°C to 44.85 ± 0.01°C, at five different wavelengths from 0.450 to 0.670 μm. They found the temperature coefficient of refractive index (dn/dT) to be essentially wavelength independent and linear with temperature. They report the ordinary coefficient to be $+8.18\times10^{-6}$/°C and $+13.40\times10^{-6}$/°C for the extraordinary index.

[a] The n_o and n_e values for wavelength 7.0 μm and smaller were calculated with the Herzberger-type formula. The n and k values for wavelength greater than 7.0 μm were calculated from the reststrahlen data. The bracketed numbers indicate the reference to the data.

Calcium Fluoride (CaF_2)

D. F. BEZUIDENHOUT
Division of Production Technology
Council for Scientific and Industrial Research
Pretoria, Republic of South Africa

X-ray diffraction analysis of calcium fluoride (CaF_2) has shown it to belong to the cubic fluorite structure. The Ca^{2+} ions are arranged in a face-centered cubic lattice and the F^- ions in a cubic lattice. Each fluorine ion is surrounded by four calcium ions and each calcium ion by eight fluorine ions [1, 2, 3]. The lattice constant a_o is given as 0.546305 nm [4], which is slightly higher than $a_o = 0.545$ nm reported by Goldschmidt [5]. Based on symmetry considerations, CaF_2 is classified under the space group $Fm3m$ (O_h^5) [6].

An early account of the growth of "artificial" CaF_2 is given by Stockbarger [7]. At present, high-purity, synthetic CaF_2 material is readily available in cylindrical form up to 200 mm in diameter [8]. However, it has been reported that large crystals of optical quality CaF_2, 600 mm in diameter, have been grown by Sokolov *et al.* [9, 10]. In a more recent publication, Horowitz *et al.* gave a correlation between growth parameters and the chemical and structural quality of CaF_2 crystals [11]. Mechanical and thermal properties of synthetic CaF_2, which are relevant from an engineering point of view, are given by Combes *et al.* [12]. Because of the physical properties of calcium fluoride, both mechanical and thermal shock should be avoided during optical processing [7, 13, 14].

The wide transmission band (0.2–9 μm) of CaF_2 leads to a multitude of applications. These applications range from dispersive elements in infrared monochromators [15], filters for reducing stray light [16] and radiation-blocking elements [17, 18], to lenses and windows [19, 20]. When used as laser elements, the tendency of water to adsorb on CaF_2 surfaces should be kept in mind [21]. However, it has been found that laser-induced desorption treatment leads to passivated CaF_2 surfaces that are highly resistant to water adsorption at room temperature [22]. During the early 1940s, CaF_2 was used in thin-film form as antireflection coatings on glass lenses [23].

More recent applications of CaF_2 include areas such as optical fibers [24] and laser host material [25].

Synthetic Calcium Fluoride

CaF_2, which is a highly ionic compound, has a wide band gap. The edge of the fundamental absorption band lies in the vacuum ultraviolet at about 12 eV [26]. Much of the X-ray and ultraviolet work has been centered on studies concerning the determination of the electronic structure of CaF_2 and on color-center phenomena [27, 28]. The forbidden energy band gap is formed by the F^- $2p$ state and the $3d$ and $4s$ states of the Ca^{2+} ions [26]. Rubloff [29] used the synchrotron radiation from a 240 MeV electron storage ring as a light source in the vacuum ultraviolet to investigate the reflectance spectrum of CaF_2 covering the photon energy range 6–36 eV. The characteristics of the reflection spectra above the fundamental absorption edge were divided into three regions. Peaks in region I (6–26 eV) arise from optical excitation of electrons in the valence band. The peaks at lower energy in the valence excitation region are caused by exciton absorption, whereas intraband transitions dominate at higher energies in region I. Although valence excitations may continue into regions II (26–30 eV) and III (30–36 eV) at higher photon energies, electrons are mainly excited from core states, which lie below the valence bands. A change to broader peaks occurs on passing from region II to III, where the spectral features are caused primarily by excitations of the core states of Ca^{2+}.

Cluster calculations on CaF_2 showed the influence of impurities on the position of the absorption edge: oxygen impurity caused transitions to appear in the region 4.3–5 eV [26]. However, the theoretical values for the excitation energies in CaF_2 associated with defects appear to be less than the experimental values [26]. The effect of impurities such as oxygen or hydroxyl ions is a sharp cutoff at 0.22 μm [30, 31].

Bontinck [32] reported on the formation of color centers in CaF_2. He identified a number of absorption bands in the visible and near-infrared regions after X-ray radiation or additive coloration at high temperatures. During investigation of the coloration and luminescence of CaF_2 crystals, Rauch *et al.* [33] found that crystals that differed relatively little as to UV absorption showed marked differences in their photoluminescence and thermoluminescence behavior. Exposure to an electric field or to X-rays also leads to a change in the absorption features of CaF_2 [34, 35]. De and Rao [35] subjected low-absorption CaF_2 crystals to a high AC (or DC) field. There seems to be a considerable interaction of the field with the crystal lattice, resulting in increased concentration of lattice defects, which increases the absorption at 0.2 μm. Furthermore, when these crystals were irradiated with X-rays, absorption bands were observed at 0.375 and 0.58 μm.

The importance of surface preparation for short-wavelength investi-

gations has been stated by two groups who have done reflectance and transmittance measurements over the absorption-edge region of CaF_2 (0.12–0.16 μm) [36, 37]. It was reported that as the surface polish is improved, the increase in transmission is greater at shorter rather than at longer wavelengths. Different types of abrasives did not play any significant role in the reflectance behavior of these surfaces at short wavelengths. However, it was suggested that fluorite powder be used for the final polishing step [36]. Furthermore, it was also stated that an adsorbed layer of water vapor might influence the reflective properties of a CaF_2 surface because the absorption of water is quite high in the 0.12–0.16 μm region.

The temperature dependence of the absorption tail was investigated over the temperature range 78–573 K [37, 38, 39]. Linear behavior was found in the shift of the absorption edge. The rate of thermal shift was expressed by Tomiki and Miyata [37] as $\Delta\lambda/\Delta T = 0.26$ Å/K at the $\alpha = 10\ cm^{-1}$ point, where α is the absorption coefficient. The transmission limit (that is, $T<1\%$) changed from 0.121 μm at 291 K to 0.1165 μm at 77 K, where the sample thicknesses ranged from 0.25–0.71 mm [38]. These facts should be kept in mind when CaF_2 is used as window material near its shortwave edge in thermal experiments. At wavelengths longer than 0.15 μm, the transmission of CaF_2 windows is not affected appreciably by temperatures up to 500 °C [40].

The reflecting power of a polished fluorite surface has been measured from 0.0927 μm to 0.1605 μm for angles of incidence varying from 45 to 85 degrees [41]. A vacuum spectrograph and a method of photographic photometry, using oil-sensitized photographic film were used. The oil layer on the surface of the film absorbs the incident extreme ultraviolet light completely and fluoresces in the near ultraviolet. It is this fluorescent radiation that exposes the film, and its intensity is proportional to that of the incident light reflected from the CaF_2 sample surface inside the spectrograph. Below 0.123 μm the reflection becomes metallic in character, and by applying the appropriate reflectance formula and a numerical method, the refractive index and extinction coefficient were determined over the 0.0927–0.119 μm region. The first absorption band below the cutoff edge of CaF_2 was identified in the vicinity of 0.1115 μm. This band corresponds to an energy of 11.12 eV, which is in good agreement with the results of later reports such as Rubloff [29], who found a reflection peak at 11.02 eV at 300 K.

The dispersion curve is anomalous from between 0.113 and 0.12 μm to about 0.109 μm, when crossing the center of the absorption band. It becomes normal again toward the shorter wavelengths, but appears to become anomalous again at 0.1 μm as the next absorption band is approached [41].

On the long-wave side of the cutoff edge, refractive-index values are given for wavelengths up to 0.1605 μm [41]. For longer wavelengths, the

publication by Malitson [42] is a most comprehensive report on the dispersive properties of CaF_2. He used a modified Gaertner precision spectrometer, fitted with reflecting optics, to measure at visible and nonvisible wavelengths. The method of minimum deviation was applied to determine refractive-index values from wavelengths of 0.2288–9.724 μm. The experimentally determined index values were fitted to a three-term Sellmeier dispersion equation of the form

$$n^2 - 1 = \sum A_j \lambda^2 / (\lambda^2 - \lambda_j^2). \tag{1}$$

The λ_j represents ultraviolet and infrared absorption wavelengths and the A_j is related to the strength of the absorption bands. The parameters of the equation are given in Table I. The dispersion formula was then used to compute the refractive index at 24 °C, at wavelengths separated by regular intervals (Table IV and Fig. 1).

Malitson [42] also investigated dispersion, chromatic abberation, and resolution. It was found that the dispersion decreases steadily with increasing wavelength, reaches a minimum at 1.5 μm, and then slowly increases again while approaching the long-wavelength cutoff. For the purpose of lens design, chromatism is therefore minimized in the region near 1.5 μm. Finally, CaF_2 was found to be an excellent choice as prism material in the wavelength range 4–9 μm.

The thermal coefficient of the refractive index was determined for the range 15–35 °C and for the range 35–55 °C [42]. The results can be summarized as follows:

(1) The value of dn/dT is negative.

(2) The dn/dT versus wavelength behavior shows a steeper slope in the ultraviolet than in the visible, indicating a shift of the ultraviolet bands toward longer wavelengths with an increase in temperature.

(3) In the visible region, increases in temperature lead to a decrease in refractive-index values.

(4) The absolute value of dn/dT tends to increase with increasing wavelength and temperature.

(5) A decrease of the absolute dn/dT values in the infrared indicates that the infrared absorption bands have also shifted toward longer wavelengths with increasing temperature.

(6) An average value of $-dn/dT$ for the temperature interval of 15–24 °C over the wavelength range 0.228–9.7 μm is 8.65×10^{-6}/°C.

The temperature coefficient of the refractive index was measured by Lipson *et al.* [43] using a laser interferometric method. The temperature

was varied over the 25–110 °C range, and the wavelengths used were those of He–Ne lasers radiating at 0.6328 μm, 1.15 μm, and 3.39 μm. The *dn/dT* behavior showed the same previously observed trends [42, 44]. The *dn/dT* data follow the theoretical model suggested by Tsay *et al.* [45], where *dn/dT* is given by an approximation of the form

$$\frac{dn}{dT}=\frac{\sqrt{\varepsilon_\infty}}{n(\omega)}\left[\left(\frac{dn}{dT}\right)_e+\left(\frac{dn}{dT}\right)_l\right].$$

$(dn/dT)_e$ and $(dn/dT)_l$ are the electronic and lattice contributions to *dn/dT*. Furthermore, it was demonstrated that the slight increase in the value of *dn/dT* is comparable to the variation of the thermal expansion coefficient with temperature.

Measurements at very high temperatures in the range 293–300 K showed that the refractive index at 0.6328 μm decreased according to the relationship

$$n_T=n_r[1-8.07\times10^{-6}(T-293)-4.27\times10^{-9}(T-293)^2],$$

where n_r is the refractive index at 293 K [46]. In the same experiment it was found that the short wavelength side of the infrared band edge shifted considerably toward higher frequencies as the temperature was increased from 293 K to 1600 K. This behavior is believed to originate from a temperature broadening of the absorption band. These measurements were carried out in argon-filled chambers.

Several processes can contribute to absorption in the transparent region of a material, between the absorption edge (due to electronic transitions) on the short-wavelength side, and the reststrahlen band (due to lattice vibrations characteristic of ionic materials) on the long-wavelength side. These processes include multiphonon absorption, where a photon is absorbed and generates two or more phonons; free-carrier absorption identified by the λ^2 dependence of the absorption coefficient on the wavelength λ; impurity absorptions, which are recognized by a sharp-line structure; and the short-wavelength tail of the reststrahlen band extending into the transparent region [47].

An explanation of what may be regarded as impurity bands in CaF_2 has been given by Wickersheim and Hanking [48]. Absorption bands were observed at 2.74, 2.79, 6.76, 7.07, and 11.36 μm after CaF_2 samples were heated in air. The band at 2.74 μm was termed the infrared OH-stretching fundamental of $Ca(OH)_2$ occurring in or on the crystal. The band at 2.79 μm was identified as the stretching vibration of hydroxyl ions occur-

ring substitutionally for fluorine in CaF_2. The bands at 6.76, 7.07, and 12.5 μm were ascribed to a surface layer of $CaCO_3$.

An exponential frequency dependence of the infrared absorption coefficient, α, was found at frequencies ω greater than several times the reststrahlen frequency ω_o [47, 49, 50]. In this region the value of α decreases from about $10\,cm^{-1}$ at a wavelength of 12.5 μm, to approximately $10^{-4}\,cm^{-1}$ at 5 μm [50]. These results were interpreted as being caused by intrinsic multiphonon absorption processes [49, 50].

Kaiser *et al.* [51] used reflection and transmission measurements to obtain information on lattice vibrations. The absorption coefficient α was calculated from the transmission according to the equation

$$T=(1-R)^2e^{-\alpha x}/(1-R^2e^{-2\alpha x}),$$

where R is the reflectivity and x the sample thickness. Over the wavelength range 16.67–8.89 μm, the value of α decreased from $200\,cm^{-1}$ to $0.4\,cm^{-1}$ at a temperature of 77 K.

The reflection band was analyzed using the classical dispersion theory [51]. According to this theory, the real and imaginary parts of the complex dielectric constant, ε' and ε'', are given by

$$\varepsilon' = n^2 - k^2 = \varepsilon_\infty + \sum_j 4\pi\rho_j\nu_j^2 \frac{\nu_j^2 - \nu^2}{(\nu_j^2-\nu^2)^2+\gamma_j^2\nu^2\nu_j^2} \tag{2}$$

and

$$\varepsilon'' = 2nk = \sum_j 4\pi\rho_j\nu_j^2 \frac{\gamma_j\nu\nu_j}{(\nu_j^2-\nu^2)^2+\gamma_j^2\nu^2\nu_j^2}, \tag{3}$$

where n is the refractive index, k the extinction coefficient, ε_∞ the high-frequency limiting value of the dielectric constant, $4\pi\rho_j$ the strength of the jth resonance, γ_j the damping constant for the jth resonance, and ν_j the resonance frequency. From this analysis a strong resonance was found at 38.91 μm ($257\,cm^{-1}$) and identified as the transverse optical phonon mode [51].

At longer wavelengths the refractive index was determined from transmission interference measurements over the range 280–600 μm [52]. An average value of n equal to 2.58 ± 0.06 was found with no indication of any dispersive behavior. The extinction coefficient was calculated from trans-

mission of a thick sample over the range 170–250 μm. Values obtained for k were around 0.034 at 170 μm and 0.017 at 320 μm.

The optical constants of CaF_2 were determined from transmittance measurements on plane-parallel slabs over the wavelength band 50–200 cm^{-1} [53]. Dispersion curves were found by fitting the expression

$$n(\omega) = (\varepsilon(\omega))^{1/2} = \{(\varepsilon_0 \nu_{TO}^2 - \varepsilon_\infty \omega^2)/(\omega_{TO}^2 - \omega^2)\}^{1/2} \tag{4}$$

to the experimentally obtained values. There are essentially two unknowns: ε_o, the static dielectric constant and ω_{TO}, the vibrational frequency at zero wave vector. The values used were $\varepsilon_\infty = 2.04$, $\varepsilon_o = 6.63$, and $\omega_{TO} = 257$ cm^{-1} at 300 K. Equation 4 was used to calculate n at 100 and 200 μm (Table IV); however, it should be noted that Eq. 4 does not take absorption into account. The absorption coefficient was found to be strongly temperature dependent. At a wavelength of 100 μm the absorption α decreases from approximate values of 50 cm^{-1} at 300 K to 4 cm^{-1} at 80 K and less than 1 cm^{-1} at 5 K [53].

Denham *et al.* [54] used a Kramers–Kronig analysis to determine the dielectric parameters ε' and ε'' from reflection-spectra measurements over the 20–100 μm range. At 200 μm an estimated reflectivity of 19.6% leads to a refractive index $n = 2.52$. In the mm range (0.4–3 mm) the absorption of CaF_2 decreases with increasing wavelength (at $\lambda = 1$ mm, $k = 5 \times 10^{-3}$) [55]. A constant refractive index $n = \sqrt{\varepsilon_o} = 2.61$ is found at wavelengths beyond 0.3 mm.

The lattice vibrations in a crystal can be classified into optic and acoustic branches. For each value of the wave vector **k** there are $3N$ branches, where N is the number of ions in the unit cell. Three of the $3N$ branches are acoustic and $3N$-3 are optic modes [56, 57, 58]. The minimal unit cell of CaF_2 is formed by two fluorine ions sitting at the center of two tetrahedra [59]. Since the unit cell contains three nonequivalent ions (one formula unit), there are nine branches in the phonon spectra of which six are due to optic modes.

A mode of vibration can absorb energy only if a mechanism exists for the coupling of vibrational motion to the electromagnetic radiation—the motion produces an oscillating dipole moment, which can be driven by the oscillating electric field of the radiation. Also, the requirements for the conservation of energy and momentum must hold [57]. To determine the optically active vibrational modes, a crystal factor group analysis [60] or the correlation method of Fately *et al.* can be used [61].

The factor group (O_h in the case of CaF_2) leads to an identification of the species of lattice vibrations in the crystal also allowing the prediction of infrared or Raman activity. The total irreducible representation for CaF_2

can be written as [61]

$$\Gamma_{CaF_2} = 2F_{1u} + 1F_{2g}.$$

Both the optic and acoustic vibrations are included in the irreducible representation given above. One of the F_{1u} modes represents the three acoustic branches and can be subtracted leading to [61]

$$\Gamma_{optical} = F_{iu}(ir) + F_{2g}(R).$$

The remaining F_{1u} representation can be classified as a doubly degenerate transverse optic mode ν_{TO}, which interacts with infrared radiation and a longitudinal mode ν_{LO} [54]. Therefore, only one (double degenerate) mode is infrared active, resulting from the sublattice of metal ions vibrating rigidly against the fluorine lattice [62]. From the measurements of Kaiser *et al.* [51], the transverse optic mode of vibration was found at $\nu_{TO} = 257\,cm^{-1}$. The frequency of the longitudinal phonon is related to the transverse vibrational mode by the Lyddane, Sacks, Teller relation [54]:

$$\nu_{LO} = \nu_{TO}(\varepsilon_0/\varepsilon_\infty)^{1/2}.$$

A value of $\upsilon_{LO} = 476 \pm 4\,cm^{-1}$ was suggested by Zernik [63].

The Raman scattering process involves the destruction of an incident photon of frequency ω_i, the creation of a scattered photon of frequency ω_s, and the creation or destruction of a phonon of frequency ω_p [57]. In wave-vector notation the Raman process can be expressed as $\mathbf{k}_i = \mathbf{k}_s \pm \mathbf{k}_p$. The mode of symmetry F_{2g} is triply degenerate and Raman-active [54]. This mode results from a stationary cation lattice with the anions undergoing displacements against each other [58]. Using shortwave (0.488–0.6328 μm) laser light to excite CaF_2 crystals, the Stokes shifted component of the Raman spectrum was found at $322\,cm^{-1}$ [59, 64, 65]. It has also been pointed out that impurities might lead to fluorescent lines, which could be misinterpreted as Raman scattering [64]. The temperature dependence of the one-phonon Raman bands has been investigated using argon-ion (0.488 μm and 0.5145 μm) and He–Cd (0.4416 μm) lasers as light sources. A shift was observed from $330\,cm^{-1}$ at 15 K to about $300\,cm^{-1}$ at 1200 K [59]. Raman spectra excited by surface polaritons were produced by 0.5145 μm light and investigated at different scattering angles θ_s [66]. The angle of incidence was 35 degrees and Raman peaks were observed from $324\,cm^{-1}$ ($\theta_s = 36.5°$) to $403\,cm^{-1}$ ($\theta_s = 38.25°$). The strongest peaks were found at $371.5\,cm^{-1}$ ($\theta_s = 37°$) and $391\,cm^{-1}$ ($\theta_s = 37.25°$).

Laser Applications

Calcium fluoride has been considered a prime candidate for use as laser windows at both short (249 nm) [67] and long wavelengths (2.8–5.3 μm) [68]. Its sensitivity to thermal and mechanical shock led to programs for

strengthening the material without degrading the optical performance over its transparent range [68, 69, 70]. A hot-forging process was developed to produce small-grain polycrystalline blanks. Forged CaF_2 has shown an increase in the crystal-fracture energy in excess of five times that of single crystals, but has the disadvantage of cloudy regions within the bulk, or so-called veiling. Microscopic investigation of a veiled area has shown it to be composed of needlelike defects, which are voids lying parallel to the boundaries of elongated grains. These defects are characteristic of the forging process [68]. A hot isostatic pressing (HIP) treatment can eliminate these voids. It was postulated that the veils migrated to the surface where the bulk material collapsed in on itself [69]. It was also concluded that HIP-processed CaF_2 showed slightly increased absorption at 2.7 and 3.8 μm, and although the optical inhomogeneity is increased at 633 nm, it is still very low. Furthermore, the visible-scattering levels are decreased by a factor of eight compared with pre-HIP material, and the infrared scatter (at 3.7 μm) was largely unaffected.

An early attempt to determine some of the optical properties of forged CaF_2 is that of Dodge [71]. The index of refraction was determined by means of the minimum-deviation method. Data were obtained at 20.8 °C and 33.6 °C from 0.25–8 μm. Each set of experimental values was fitted to a three-term Sellmeier dispersion equation (Eq. 1). Emphasis was placed on obtaining a mathematical fit of the measured data, and the λ_j and A_j values are not intended to have any physical significance. These values are given in Table III. A comparison of Dodge's results [71] with those of Malitson [42] shows a minimum difference between 0.7 and 0.9 μm ($\Delta n = 0.5 \times 10^{-5}$) and a maximum difference ($\Delta n = 6.6 \times 10^{-5}$) at 0.28 μm and 4.8 μm. The index variation at 0.28 μm is attributed to a weak absorption band near 0.3 μm in the forged CaF_2. A possible absorption band between 4 and 5 μm was considered to be the reason for the difference at 4.8 μm. It must also be stressed that Dodge's [71] investigation should be regarded as a case study of a specific piece of CaF_2 material.

A photoacoustic study of the absorption properties reveals that surface absorption was found to be strongly wavelength dependent [72]. In the 2.7 μm region the surface absorption becomes dominant over bulk absorption. In another experiment both a photoacoustical and a laser-calorimetry method were used to determine bulk and surface absorption values at 1.3 μm [73]. Photoacoustic values of $\alpha_{\text{bulk}} = 6.8 \times 10^{-4}\,\text{cm}^{-1}$, $\alpha_{\text{surface}} = 4.8 \times 10^{-5}\,\text{cm}^{-1}$ compared closely with calorimetry values $\alpha_{\text{bulk}} = 6.14 \times 10^{-4}\,\text{cm}^{-1}$ and $\alpha_{\text{surface}} = 8.36 \times 10^{-5}\,\text{cm}^{-1}$ [73]. The optical absorption coefficient α measured at DF (3.8 μm) and HF (2.7 μm) wavelengths showed that single-crystal material has a slightly lower absorption than the forged material; the results for the absorption obtained from a variety of commercial CaF_2 samples indicate a variation in α obtained from different suppliers [74]. An investigation into the surface spectral distribution of

extrinsic absorption in highly transparent solids revealed that the atmospheric contaminants identified on CaF_2 surfaces could be grouped as hydrocarbons (3–4 μm), CO_2 (4.2 μm), liquid water (around 6 μm), and carbides (6.8 μm) [75]. The results obtained by Fernelius *et al.* [73] (that $\alpha_{surface} < \alpha_{bulk}$) might be ascribed to the fact that atmospheric contaminants at 1.3 μm are much less absorbing than at other wavelengths, such as the excimer UV region or 2.7 μm in the infrared, for example. Also, surface preparation, that is, polishing and cleaning before the tests, plays an important role in the experimental results of surface absorption measurements. In an experiment in which the absorption of CaF_2 was measured by laser calorimetry, it was found that hydrofluoric-acid cleaning reduced the surface absorption of the samples substantially [76]. It was suggested that contamination from the polishing process or the presence of calcium oxides on the sample surfaces led to the relatively high precleaned absorption values [76]. The presence of smooth, undamaged surface layers (<20 nm thick), which cover the subsurface damage on polished CaF_2, was illustrated by Law *et al.* [77].

Damage in CaF_2 optics used at excimer wavelengths may manifest itself in bulk and surface damage or in the generation of color centers. A laser damage experiment was carried out using a 0.249 μm, 3 ns excimer laser with an output pulse energy of around 700 mJ [67]. Work on the surface finish of CaF_2 surfaces indicated that the damage threshold is not as dependent on surface topography as it is on surface cleanliness, which is by far the greatest factor affecting damage thresholds [67]. For instance, it was suggested that the most important role of cracks is to act as a trap for absorbing impurities. Work done on highly pure CaF_2 crystals and naturally occurring fluorspar led to the conclusion that the presence of rare earth 3^+ ions is crucial in the formation of color centers [67]. XeF laser-damage experiments were used to measure damage thresholds for bare polished crystals of CaF_2 [78]. Damage was induced by applying 1000 pulses ($\lambda = 0.35$ μm, 25 ns) to small sites (0.12×0.03 cm) on the surfaces of the samples. Fluorescence-free CaF_2 exhibited both surface and bulk damage at 10 J cm^{-2}, whereas UV-grade CaF_2 showed only surface damage at 10 J cm^{-2}. From the damage morphology on the UV grade samples, it was suggested that improved polishing methods could lead to higher surface-damage thresholds. Laidler and Emmony [79] demonstrated the effect of rare-earth impurities on the ultraviolet wavelength absorption (0.339 μm) of CaF_2. It was found by these authors that pulsed laser damage thresholds (at 0.248 μm) indicated that the impure crystals had a higher damage threshold than the pure ones at certain dopant levels. It was suggested that the impurities, which act as electron acceptors, or holes formed by these impurities, continually trap conduction electrons and therefore hinder the buildup of an efficient electron avalanche process [79].

At infrared wavelengths the laser-damage threshold of CaF_2 was investi-

gated using pulsed DF laser light with three dominant lines at 3.8 μm [80]. The temporal pulse width was approximately 75 ns and a single-shot, one-site method was used. The peak on-axis intensity that damages CaF_2 was 25 GW/cm^2. What is more important, though, are the conclusions that the surface-damage thresholds are much lower than the bulk-damage thresholds, and that the damage-site morphology suggests that inclusions or defects are responsible for the damaging interaction [80].

It is clear that special attention must be given to surface preparation such as polishing and cleaning, in order to obtain CaF_2 laser components that will withstand high laser power densities.

Thin Films

Films a few thousand angstroms thick, grown by physical vapor deposition, were investigated by X-ray diffraction for a number of different coating conditions [81, 82]. It was found that when the substrate temperature was maintained at 25 °C during evaporation, the (111) planes were orientated approximately parallel to the glass substrate surface. For a substrate temperature of 110 °C the (110) planes were strongly oriented parallel to the surface, and this orientation of the (110) planes persisted for temperatures up to 310 °C [81, 82]. Stress measurements showed a high initial tensile stress, which rapidly fell to a low value as the thickness increased [83].

When the substrate temperature was kept below 100 °C during coating, the film showed a refractive index as low as about 1.26 [23]. These films tended to be very soft. At substrate temperatures between 280 and 300 °C, hard, robust films were formed with an estimated refractive index of 1.4. When the substrate temperature was 330 °C, films with a refractive index of approximately 1.42 resulted [23]. In a review of ultraviolet coating materials the refractive index of CaF_2 was given as 1.23–1.46 at 0.55 μm [84].

Bousquet [85] found that the reflectances of CaF_2 films at the half-wave positions are invariably lower than those of the substrate, where $n_f < n_s$. This result has been interpreted by Heavens and Smith as being caused by films having a gradient of refractive index normal to the substrate surface, with the index decreasing as the air–film surface is approached [86].

The laser-damage threshold of CaF_2 films was found to increase with an increase in both wavelength and pulse width [87]. At 0.265 μm, threshold values of 2.29 J cm^{-2} (5 ns pulse width) and 3.55 J cm^{-2} (15 ns pulse width) were found. Corresponding threshold values at 1.06 μm are 20 J cm^{-2} and 33 J cm^{-2} (pulse width 5 ns and 15 ns, respectively). These results were obtained for $\lambda/4$ films ($\lambda = 1.06$ μm).

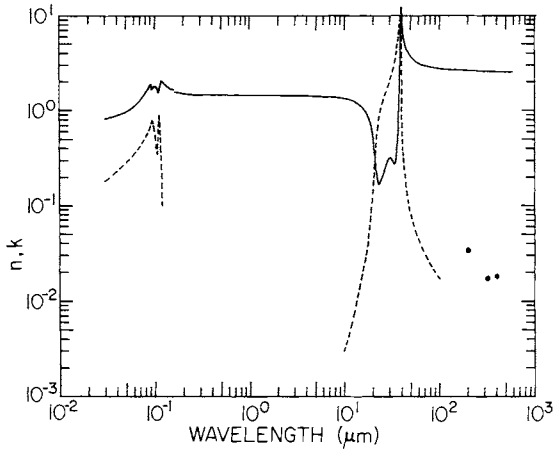

Fig. 1. Log–log plot of n (solid line) and k (dashed line) versus wavelength in micrometers for calcium fluoride.

TABLE I

Constants of the Dispersion Equation Used by Malitson [42]

$\lambda_1 = 0.050263605$	$A_1 = 0.5675888$
$\lambda_2 = 0.1003909$	$A_2 = 0.4710914$
$\lambda_3 = 34.64904$	$A_3 = 3.8484723$

TABLE II

A List of Parameters Used to Calculate the Dispersion Values in Table IV from 1000 cm^{-1} to 100 cm^{-1} [51]

Parameter	Value
ν_1	257 cm^{-1}
γ_1	0.018
$4\pi\rho_1$	4.2
ν_2	328 cm^{-1}
γ_2	0.35
$4\pi\rho_2$	0.4
ε_∞	2.045

TABLE III

Constants for Dispersion Equations Used by Dodge at a temperature of 20.8 °C [71]

$\lambda_1 = 0.07218116$	$A_1 = 0.98584551$
$\lambda_2 = 0.14114719$	$A_2 = 0.05290246$
$\lambda_3 = 36.465937$	$A_3 = 4.2816899$

TABLE IV

Values of n and k for Calcium Fluoride obtained from various references[a]

There is considerable nomenclature confusion concerning these films, which various authors have attempted to rectify. Although there is no general consensus on terminology, they are often referred to as "a-C : H" or "diamondlike" carbon or "DLC." Here we will use the terms a-C : H and DLC interchangeably. Unfortunately, they are also being confused recently with diamond films. Amorphous hydrogenated carbon (a-C : H) has 20–55 percent hydrogen, and an optical band gap (determined from Tauc plots) between 0.5 and 3.0 eV. Diamond films nominally contain no hydrogen, are polycrystalline, and form only at high temperatures. a-C : H films are typically formed by plasma or ion-beam deposition (using hydrocarbon gas) onto substrates maintained at room temperature or slightly

above room temperature. There are other preparation techniques as well [1–30]. There is considerable general literature on these films, including reviews [1, 2, 5, 6, 10, 17, 26, 27]. a-C : H (DLC) films graphitize above a few hundred degrees Celcius [31].

The properties of DLC, including optical constants, depend strongly on preparation conditions. Thus, the user can prepare samples with an optical gap anywhere in the 0.5–3.0 eV range, but most easily in the 1–2 eV range. Associated with this is the control of index of refraction from approximately 1.7 to 2.2, and a related extinction-coefficient dependence.

DLC is generally transparent for wavelengths greater than mid-visible. In the infrared there are resonant hydrogen absorptions in several spectral ranges, but with minimal absorption in other ranges [1–2].

Readers should carefully compare their preparation techniques and conditions before using data from the literature or from the table displayed in this critique. We have included the dependence of optical constants on substrate and/or annealing temperature, since this is a commonly varied parameter, which results in large property changes.

We have chosen to present the optical data of plasma-deposited DLC in tabular form, as well as the constants of a fit to the experimental data according to the theory given by Forouhi and Bloomer [24, 32]. Table I gives the constants in the following equations for index of refraction n and extinction coefficient k:

$$n(E) = n(\infty) + [B_0 E + C_0]/[E^2 - BE + C] \tag{1}$$

$$k(E) = A(E - E_g)^2/(E^2 - BE + C), \tag{2}$$

where E is photon energy, and E_g is the optical band gap, both in eV. Also,

$$B_0 = (A/Q)[-B^2/2 + E_g B - E_g^2 + C], \tag{3}$$

$$C_0 = (A/Q)[(E_g^2 + C)B/2 - 2E_g C], \tag{4}$$

and

$$Q = \tfrac{1}{2}(4C - B^2)^{1/2}. \tag{5}$$

The values of the constants in Table I are given for films prepared by

30 kHz plasma deposition from CH_4 on silicon substrates held at room temperature using powers of 50–200 W with subsequent annealing at 400, 600, and 750°C [24]. In all depositions the flowing CH_4 pressure was held at 315 m torr. Data were taken over the range 1.5–4.1 eV. Extensions of Eqs. 1 and 2 beyond this range should be done cautiously.

Table II gives the measured data for selected samples described above, but in tabular form. Fig. 1 is a plot of n and k. These data were taken by variable-angle spectroscopic ellipsometry (VASE) (for which no Kramers–Kronig analysis is required), assuming a model of a single film on a substrate. These results are highly reliable with the exception of very low values of k; it is difficult to measure k accurately by ellipsometry for values less than about 0.02.

Infrared optical-constant data for samples prepared in the same deposition system for data given in Tables I and II are given in Table III [6, 28].

For completeness, we also include optical constants of a-C:H in the 1.5–4.75 eV spectral range prepared in a dc glow discharge from C_2H_2 deposited on quartz held at 250°C with anneal at 350°C, as well as with no further anneal [3]. These are shown in Table IV. Fig. 2 is a plot of n and k. In the original reference the reader can find data for samples annealed to even higher temperatures [3]. These are not repeated here, due to the expected partial graphitic transformaton of the DLC films at higher than about 400°C [31].

In addition to data presented above on plasma-deposited films, we present data in Tables V and VI on diamondlike films made by a low-energy, ion-assisted deposition (IAD) technique based on unbalanced dc magnetron sputtering. Fig. 3 is a plot of n and k from Table VI. Details of the preparation technique are given in Refs. [5, 33–35]. The optical properties of these films are sensitive to both the ion energy per deposited carbon atom, and (as for all diamondlike carbon) the hydrogen content. These films were deposited at 300 K onto quartz substrates, and the optical constants were determined from transmittance and near-normal reflectance measurements in the photon energy range 0.5–7.3 eV. Measurements were made at room temperature (295 K). The relative measurement accuracy is about 1% except at the UV extreme (>6.5 eV) where it is a bit worse. Table V gives preparation parameters for nine different samples, but detailed data are given only for sample numbers 1, 5, and 9. These three were selected because they represent a range of hydrogen concentration and therefore a range of optical properties. Notice the trend toward increasing optical band gap with increasing hydrogen content C_H. The original references [5, 33–35] can be consulted for information on the remaining samples.

Finally, we present in Table VII the optical constants of arc-evaporated carbon films [36, 37]. These are amorphous and nominally contain no hydrogen; these are *not* called "a-C:H," "DLC," or "diamondlike"

carbon. The reader can see from the table that these films are very different from DLC, for example, in the lack of an optical absorption edge.

Cesium Iodide (CsI)

JOHN E. ELDRIDGE
Department of Physics
University of British Columbia
Vancouver, British Columbia, Canada

The room-temperature values of n and k tabulated here (Table I, Fig. 1) were obtained from the following works and references therein: in the millimeter region, an individual measurement of n at 2 mm (5 cm^{-1}) is from Dianov and Irisova [1]; both n and k at selected points in the submillimeter region, 300 GH_z (10 cm^{-1}), 500 GH_z (16.7 cm^{-1}) and 700 GH_z (23.3 cm^{-1}) are from Bystrov *et al.* [2]; values of k in the far-infrared region at 14–56 cm^{-1} and at 94–200 cm^{-1} are from Beairsto and Eldridge [3]; over the reststrahlen peak, from just below 60 cm^{-1} to 94 cm^{-1}, n and k are given by Vergnat *et al.* [4], and values of n are continued into the wings by the same authors [4, 5]; in the transparent region, which covers the infrared and the visible from 67 μm (149 cm^{-1}) to 0.25 μm (40,000 cm^{-1}), values of n are from Li [6], who relied mainly on the data of Rodney [7]; in the vacuum ultraviolet from 5 eV (0.25 μm) to 11.4 eV (0.11 μm) n and k values are from Said and Green [8]; in the low-energy X-ray region from 100 eV (124 Å) to 2000 eV (6.2 Å), *calculated* values of n and k are from Henke *et al.* [9].

Cesium iodide has the lowest-energy reststrahlen band of all the alkali halides and common diatomic optical-window crystals, with a room-temperature peak in extinction coefficient, k, near 63 cm^{-1} (159 μm, 7.8 meV. Apart from the structure in this strong and relatively broad resonance, there is, of course, no other intrinsic absorption until electronic transitions in the vacuum ultraviolet. For this reason it is a common window material in infrared spectroscopy, providing the largest range to low energies in the far-infrared region, (for example, a window of 3 mm thickness will transmit down to approximately 150 cm^{-1}). Although it is very soft, with some care it can be used with indium O-rings for low-temperature studies. Since the absorption in the wings falls off very rapidly, the intrinsic absorption in the infrared region is extremely low, offering promise for CsI, as a low-loss, light-guide material and as windows for high-intensity laser beams.

The reststrahlen band is due to the only optically active vibration in the crystal, the doubly degenerate, transverse-optic (TO) mode with zero wave vector, which has a frequency inversely proportional to the reduced mass of Cs and I. The structure in the wings is due to the frequency-dependence of the damping of this TO mode. This damping, in turn, is due to the two- and higher-phonon processes by which the TO mode can relax when energy and momentum are conserved. Calculations of this damping for CsI, and the resulting absorption through the reststrahlen band, give good agreement with the experiment data [10, 3]. The most accurate method of measuring n and k in this region would be that of dispersive-reflection spectroscopy (also known as asymmetric Fourier-transform spectroscopy), which was used in the investigations of NaCl and KCl, as well as some of the semiconductors reported in *HOC I.* In such a method n and k are measured directly, without the need for a Kramers–Kronig analysis or a fit to several fictitious Lorentzian oscillators. No such experiment has, however, been performed so far for CsI. The peak values of n and k reported here have therefore been obtained from a Kramers–Kronig analysis of the power reflectivity [4], which necessarily misses much of the two-phonon structure in n, above the resonance where n is small.

Starting at the lowest energy, Dianov and Irisova [1] measured n at 2 mm (5 cm^{-1}) at 300 K and 77 K with a Michelson interferometer. The room-temperature value agrees with that measured at 300 GH_z (10^{-1}) by Bystrov *et al.* [2] using an "Epsilon backward-wave-tube submillimeter spectrometer." They also reported n and k values at 500 GH_z (16.7 cm^{-1}) and 700 GH_z (23.3 cm^{-1}). The k values agree with those obtained by Beairsto and Eldridge [3] from transmission measurements through single crystals in a Michelson interferometer. Samples ranged in thickness from 0.007 cm to 0.8 cm. They were cut with a wire saw and then polished using jeweller's rouge in ethylene glycol. After polishing, they were cleaned in acetone and then trichloroethylene. k was obtained from $\alpha/4\pi\bar{\nu}$, and α was extracted from the expression for the transmitted intensity, I, given by

$$I=\frac{I_0(1-R)^2(1+k^2/n^2)e^{-\alpha d}}{1-R^2e^{-2\alpha d}}. \tag{1}$$

Measured values of R were used. The term $(1+k^2/n^2)$ is negligible except when close to the resonance on the high-frequency side. These results show k to be fairly smooth below the resonance, but Love *et al.*'s accurate low-temperature measurements on KI crystals up to 10 cm long [11] show that two-phonon structure can be observed in these materials.

The thinnest crystal used in Ref. [3] did not transmit between 56 cm^{-1} and 94 cm^{-1}. The two models used in the reflectivity analysis [4, 5] give n

and k values that can differ by up to 50%. The Kramers–Kronig values [4] are tabulated, since they are more directly obtained, but these are supplemented with Lorentz-model values [5] in the wings. The accuracy in the wings is poor and, as has been mentioned, structure is missing above the resonance. The reflectivity measurements were performed on a 15° wedged single crystal, and the authors report a 3% reproducibility.

In the wide transparent region from 67 μm (150 cm^{-1}) to 0.25 μm (40,000 cm^{-1}), Li [6] has tabulated very accurate values of n. Starting with the 297 K data of Rodney [7], which Li reduced to 293 K, and using the infrared absorption peak at 161.29 μm (detailed earlier [4]), together with the seven known absorption peaks in the vacuum ultraviolet, Li fitted the following dispersion equation of the Sellmeier type,

$$n^2 = 1.27587 + \frac{0.68689\lambda^2}{\lambda^2-(0.130)^2} + \frac{0.26090\lambda^2}{\lambda^2-(0.147)^2} + \frac{0.06256\lambda^2}{\lambda^2-(0.163)^2} + \frac{0.06527\lambda^2}{\lambda^2-(0.177)^2} + \frac{0.14991\lambda^2}{\lambda^2-(0.185)^2} + \frac{0.51818\lambda^2}{\lambda^2-(0.206)^2} + \frac{0.01918\lambda^2}{\lambda^2-(0.218)^2} + \frac{3.38229\lambda^2}{(\lambda^2-161.29)^2}, \quad (2)$$

where λ is in μm. Values from Eq. 2 are tabulated, although to greater accuracy than warranted by the experiment for the purpose of smoothness and internal comparison. Rodney's measurements of minimum deviation were performed on a 25° prism sample, loaned by the Harshaw Chemical Company, in two temperature-controlled spectrometers. The precision of the index measurements was reduced by the small wedge angle, since 60° is closer to the optimum, and instrumental factors reduced the wavelength accuracy when broad reference bands were used. Only the third decimal place is meaningful between 67 μm (150 cm^{-1}) and 50 μm (200 cm^{-1}), and the fourth decimal place elsewhere. The estimated uncertainty decreases from 1×10^{-3} at the low-energy limit to 1×10^{-4} near the high-energy limit. As an example of this accuracy, comparison may be made with the results of Selvarajan *et al.* [12], who later performed similar measurements at 300 K and 80 K over the smaller range from 30 μm^{-1} (333 cm^{-1}) to 2 μm (5000 cm^{-1}). After correcting for the temperature difference, these results agree to within $2–3 \times 10^{-4}$ with those of Li, the former being consistently higher.

No measurements of k beyond 200 cm^{-1} have been found. Measurements of the absorption in the transparent region have, however, been performed

using laser calorimetry, but these have all measured impurity absorption. Plotnichenko *et al.* [13] measured the volume absorption coefficient at several laser wavelengths, yielding k values of 7.6×10^{-10}, 4.4×10^{-10}, and 7.6×10^{-10} at $10.6\,\mu$m ($943\,\text{cm}^{-1}$), $5.54\,\mu$m ($1805\,\text{cm}^{-1}$), and $1.06\,\mu$m ($9433\,\text{cm}^{-1}$), respectively. Even though very small, and claimed by the authors to be the lowest value at $10\,\mu$m of any infrared material, these values are still orders of magnitude higher than the calculated intrinsic k due to the combination of multiphonon absorption and Mandel'shtam–Brillouin scattering.

In the vacuum ultraviolet, n and k are given by Said and Green [8] at 300 K and 25 K between 5 eV ($40{,}330\,\text{cm}^{-1}$, $0.248\,\mu$) and 11.4 eV ($91950\,\text{cm}^{-1}$, $0.11\,\mu$m). These were obtained by a Kramers–Kronig analysis of the power reflectivity. In this region the principal features of the reflectivity spectrum are due to excitons and the lower interband transitions, since the direct band gap between the valence-band maximum and the conduction-band minimum is calculated to be about 6.4 eV. There are seven discernible broad features, as mentioned in Li's fit to Eq. 2, which sharpen considerably at 25 K, revealing further structure. After unsuccessful attempts to cleave the samples *in situ*, Said and Green mechanically polished them with fine alumina in mineral oil, thoroughly cleaned them in an ultrasonic bath to remove the aluminum, and kept them in high vacuum until required. Prior to insertion in the reflectometer, the samples were annealed for several hours at 400 K to remove any surface damage. Their results have been read from the graphs at 0.1 eV intervals and have been tabulated. They differ considerably from the results of Lamatsch *et al.* [14] between 2500 Å (5 eV) and 2000 Å (6.2 eV). Lamatsch *et al.*'s results were obtained by analyzing the transmission and reflection spectra of a thin film. Although the two features in this interval are similar to those in Ref. [8], n and k values disagree by more than a factor of two. Lamatsch *et al.* also noticed discrepancies in magnitude between the reflection spectrum obtained from a bulk sample and that calculated from their thin-film values of n and k. They attributed these discrepancies to the different effect that localized excitons have on the absorption spectra of films and bulk samples. Only the bulk-sample data from Ref. [8] have therefore been tabulated here.

Beyond 11.4 eV, no values of n and k have been found. Many studies of total absorption have been performed, usually through thin films, which yield spectra of the absorption coefficient μ either in arbitrary or in absolute units. Those performed before 1977 have been summarized by Haelbich *et al.* [15]. These spectra are very similar to the k spectra, as may be seen by comparing the work above in Ref. [8] at 25 K with the 10 K μ spectra of Teegarden and Baldini [16], so that the structure in k, if not the absolute magnitude, may be found. In particular, Saito *et al.* [17] give μ in arbitrary units at room temperature between 12 eV and 24 eV; Cardona *et*

al. [18] give absolute values of μ between 50 eV and 190 eV; Lukirskii and Zimkina [19] give μ in arbitrary units between 50 eV and 500 eV; and Sugiura and Kiyono [20] give μ in arbitrary units at the Cs and I X-ray L edges around 5 kV.

For several materials, good agreement has been found previously in the soft X-ray region between experimental values and those calculated using the atomic-scattering factors of Henke *et al.* [9] (see, for instance, Ni, Ag, Au, and SiO_2 in *HOC I*). We have therefore tabulated the calculated values of n and k for CsI between 100 eV and 2000 eV, which includes the M absorption edges. In scattering theory, the refractive index is given as

$$n = 1 - \delta - i\beta, \tag{3}$$

where

$$\delta = \frac{r_0 \lambda^2}{2\pi} N \bar{f}_1$$

$$\beta = \frac{r_0 \lambda^2}{2\pi} N \bar{f}_2. \tag{4}$$

Here, $r_0 = e^2/mc^2$, the classical electron radius, equal to 2.814×10^{-13} cm; N is the density of atoms per unit volume; and $\bar{f}_1$ and $\bar{f}_2$ are the sum of the scattering factors, which are listed in [9].

[a]Tabulation of n and k as a function of photon energy (electron volts), wave number (inverse centimeters), and wavelength (Angstroms or micrometers). References for the data are given in brackets and apply to all data below the brackets until a new reference appears; k is often very small and exponents are given for numbers smaller than 10^{-2}. The power of 10 applies for all data below the exponent until a new exponent appears or the exponent becomes 10^{-1}, whereupon the number is given in decimal form.

Copper Oxides (Cu_2O, CuO)

CARL G. RIBBING and ARNE ROOS
Institute of Technology
Uppsala University
Uppsala, Sweden

The established stoichometric copper oxides, cuprous oxide, Cu_2O ("red") and cupric oxide, CuO ("black"), form cubic and monoclinic unit cells in their respective equilibrium crystalline forms [1]. Reports on the phase $CuO_{.67}$, described as a gross defect structure of Cu_2O, are found in the literature [2, 3], but will not be considered here. It has furthermore been claimed that Cu_2O is actually not an equilibrium structure at temperatures below 375 °C and therefore decomposes very slowly at room temperature into metallic copper and cupric oxide [4]. The Cu-O phase diagram is markedly pressure dependent, such that a CuO layer transforms into Cu_2O and eventually into metallic copper when placed in vacuum.

Cuprous oxide is a semiconductor with a direct band gap of 2.17 eV. It has been the object of several basic studies concerning optical-band-gap absorption, its temperature dependence, and the interpretation of the low-temperature absorption line spectrum below the gap as transitions to excitonic levels [5–7]. The partly ionic character of the bonding causes structures in the optical functions in the infrared spectral region. The strongest IR-active mode, corresponding to the residual-ray region, was located at 609 cm^{-1} (16.4 μm) [8]. A secondary lattice mode at 146 cm^{-1} (68 μm) is reported for polycrystalline samples [9]. Several other lattice modes have been identified in later work and attributed to defects, impurities, and nonstoichiometry, and somewhat varying positions of the major lattice mode are given in the literature, which also include several Raman studies [9–11]. The recent discovery of high-temperature superconductors in which a key role seems to be played by the copper oxide in the formation of Cooper pairs has renewed the interest in the infrared properties of the copper oxides [12].

Considerably less has been reported about the black cupric oxide CuO. It is also a semiconductor, obviously with a smaller optical band gap than the red oxide. The values reported in the literature vary within the range 1.2–1.5 eV. A wet photoelectrochemical technique was used to obtain an indirect energy gap of 1.35 eV [13]. Early measurements on a bulk,

polycrystalline sample, sintered in an oxygen atmosphere, resulted in an absorption edge too shallow to define an energy gap [14]. Simultaneous measurements on reactively sputtered films were also used to derive the optical constants without specifying an energy gap [15]. Recent transmittance measurements versus thickness on thin films prepared by rf, reactive sputtering gave an energy gap value of $1.21 \pm .05$ eV [16].

Much of the work on the physical properties of the copper oxides has been motivated by various technical applications. Cuprous oxide was one of the very early model semiconductors, and the discovery of the Cu_2O–Cu rectifier dates back to 1920 [17]. The use of cupric oxide on copper as a photoelectric and/or photoconductive material was suggested even earlier [18]. It is still of technical interest [19] to utilize this metal–oxide system as a possible low-cost solar cell. Oxidizing copper has furthermore been one of the alternatives to prepare the selectively absorbing surface of a thermal solar collector [20]. In this application the black oxide results in higher efficiency owing to its higher absorption of solar radiation. Several methods have been used to oxidize a copper base giving optimum performance in terms of selectivity and stability [21], and the use of a warm mixture of acids has been commercialized [22]. It has been demonstrated that the wet-oxidation techniques result in a rough interface between the oxide and the metal, which significantly increases the solar absorption [23, 24].

The ease with which oxidation of copper can take place is partly a corrosion problem, but it is also one of the reasons for the technical interest in this system. Even relatively thick layers of copper can be transformed into either one of the stoichiometric oxides, merely by heating in air. The green hue of old copper roofs is often (but incorrectly) said to be due to copper oxide. Instead, this surface is formed in the presence of water together with some other substances. It consists mainly of copper hydroxysulfate or, especially in coastal areas, copper hydroxychloride. From a basic point of view, the fact that copper is an easily oxidized noble metal with the typical strong tendency for diffusion creates a strong incentive for careful studies of the oxidation mechanism, rate laws, temperature dependence, and so on. The literature on the oxidation of copper is therefore very rich [25–28]. Copper is also a suitable metal for the study of laser-oxidation techniques [29, 30].

The thermal oxidation of copper, in contrast to wet oxidation, produces a rough oxide–metal interface that is *not* absorbing, but causes strong light scattering in the visible and near-infrared regions. The amount of scattering and its conspicous spectral dependence was used to determine the RMS roughness amplitude of both the air–oxide and oxide–metal uncorrelated interfaces [31, 32]. Here the Cu_2O–Cu served as a model system because of the exceptional magnitude of the light scattering.

For reasons made obvious above, there is a wealth of published optical constants for the cuprous oxide in the visible and near-infrared spectral

regions and considerably less data for cupric oxide in the same spectral regions. It has not been possible to find published optical constants for either one of the copper oxides in the vacuum UV or soft X-ray regions, however. Tables I and II and Figs. 1 and 2 therefore cover only the near UV, down to 300 nm. The valence bands and the core-level positions have been determined by electron spectroscopy as part of basic investigations about satellite formation in photoelectron spectra [33, 34]. Without knowledge of the numerical values of the optical functions, we can predict that they will exhibit oscillator structures, in the case of CuO around the core levels: O(1s)-530 eV ($\lambda = 2.34$ nm), Cu($2p_{3/2}$) − 933 eV (1.33 nm) and Cu($2p_{1/2}$) − 954 eV (1.30 nm). In Cu_2O there is a 1.2 eV chemical shift in the copper levels toward lower binding energy whereas the O(1s) is unchanged.

For the cuprous oxide in the visible region, data have been selected for thermally oxidized copper films, which have been prepared in different thicknesses to allow combined R and T measurements. The optical thickness nd was calculated from the position of the interference fringes, and the refractive index was determined from their envelope function in the region of low absorption. The values from Ref. [35] cover the broadest region and are somewhat higher than the data from Refs. [36] (electrodeposited), [37], and [14]. The values given are also marginally higher than those obtained from the dispersion relation [36]

$$n^2(\lambda) = 1 + A\lambda^2/(\lambda^2 - B),$$

which can be used for wavelengths longer than 0.550 μm; here, $A = 4.81$ $(\mu m)^{-2}$ and $B = 0.125$ $(\mu m)^2$. At shorter wavelengths this relation gives values that are too high, however. The k values are significantly lower than those obtained for sintered powder [14] and slightly higher than those of Ref. [37].

The optical constants given here for cupric oxide have also been determined for thermally oxidized copper films [35]. In the visible part of the spectrum, the n and k values are in good agreement with those of Ref. [3]. In contrast, both functions are significantly lower than those of Refs. [2] and [14] as well as those for *rf* reactively sputtered films in Ref. [16].

For the cuprous oxide in the infrared, optical reflectance measurements on single crystals [8, 11] or polycrystalline films [9] were performed. Kramers–Kronig analysis of these spectra [11] or additional transmittance measurements on polycrystalline films [8, 9] were used to derive the optical constants in the vicinity of the resonance frequencies. It was found that the Lyddane–Sachs–Teller relation was valid for cuprous oxide, and the dielectric constant ε_0 is equal to 7.4 in the low-frequency region [11]. The ε_0 value given by O'Keeffe [8] ($\varepsilon_0 = 6.46$) does not take the low-frequency

resonance at 146 cm^{-1} into account, but is in excellent agreement with the ε_∞ value ($\varepsilon_\infty = 6.5$) for this resonance.

It has not been possible to find published values of n and k in the infrared region for cupric oxide. Poling [38] reports absorbance spectra for CuO without giving the n and k values. The oxide exhibits an intense single band around 510 cm^{-1}. This is the only significant band in the 230–4000 cm^{-1} region.

Magnesium Aluminum Spinel ($MgAl_2O_4$)

WILLIAM J. TROPF and MICHAEL E. THOMAS
Applied Physics Laboratory
The Johns Hopkins University
Laurel, Maryland

Magnesium aluminum spinel (the mineral spinel) is face-centered cubic material, the prototype for the spinel structural family, which includes binary oxides, sulfides, selenides, as well as many other materials (see ALON, this volume). The space group is O_h^7 or $Fd3m$, unit cell length is 0.8084 nm, and the unit cell has eight formula units (56 atoms). Theoretical density is 3.58 g/cm^3, and melting point is 2378 K [1] to 2408 K [2].

In the normal spinel structure, magnesium ions occupy tetrahedral sites with T_d symmetry, aluminum ions occupy distorted octrahedral sites with D_{3d} symmetry, and the oxygen ions are at sites with C_{3v} symmetry. The positions of the ions in the unit cell have been determined by both X-ray and neutron diffraction techniques [3–6].

There is also an "inverse" spinel structure, wherein the aluminum ions occupy both T_d and D_{3d} sites, and the magnesium ions occupy some of the D_{3d} sites. The occurrence of the normal, inverse, or in-between structure depends on ionic size, method of preparation, and composition. Natural magnesium aluminum spinel has the normal spinel structure, although there is evidence that synthetic forms of spinel prepared at high temperature have the inverse structure [5, 7]. Disordering in both natural and synthetic near-stoichiometric spinel crystals is apparently caused by heating [7, 8], the structural transition taking place at 750–800 °C. This transition is apparently irreversible.

The composition of magnesium aluminum spinel varies from near-stoichiometric to highly alumina-rich. The compositions have the general formula $MgO \times mAl_2O_3$, where m varies from 0.9 up to 4. All formulations have the spinel structure (with vacancies at octrahedral sites when $m \neq 1$), with the lattice constant continuously decreasing as m goes from 1 to 3.5 [3, 9]. As m increases above 1, cation vacancies appear and typically occupy octrahedral sites [5].

Spinel is a naturally occurring mineral, sometimes with gem quality. Optical-quality spinel can be synthetically made with a variety of techniques, including growth using the Czochralski method [10], the gradient-furnace technique [11], as well as by hot pressing of powder [2, 12], press forging [13], flame fusion (Verneuil method) [3, 14], and fusion casting [15].

Little information on optical constants in the electronic region is available. Summers *et al.* [16] report an absorption edge (onset of significant electronic absorption) 7.75 eV. Woosley *et al.* [17] report a band gap of about 9 eV, with evidence of exciton formation in the 6–8 eV range, band-to-band transitions begining at 8–9 eV, and photoemission from the top of the valence band beginning at energies above 11 eV. The valance band is estimated by Woosley to be 8–9 eV wide.

Refractive-index measurements of natural spinels were made by Schlossmacher [18], who reported real and imaginary parts of the index of refraction for red-, blue-, and violet-colored crystals. Index data from the lowest absorption ("bright red") natural crystal agrees well with recent measurements (see below). Wickersheim and LaFever [19] report that the index of refraction increases with greater alumina content. They found an index of 1.708 for stoichiometric spinel and 1.717–1.720 for alumina-rich ($m=3.5$) commercial spinel using a blue filter. Roy and Hastert [2] reported visible and IR measurements made by Kodak on artificial spinel. Visible and near-IR measurements agree well with other data, but the accuracy of IR measurements above 1 μm is doubtful. Vadem *et al.* [20] measured the refractive index of stoichiometric and nonstoichiometric ($m\approx 2.7$) spinel at 0.5893 μm and obtained values of 1.718 and 1.724, respectively. They also measured the pressure and temperature dependence of their samples, obtaining dn/dT of 9.05×10^{-6} for stoichiometric and 9.34×10^{-6} for nonstoichiometric spinel.

Recent index-of-refraction measurements of Coors Optical Systems Company's stoichiometric spinel made in the UV and visible by General Dynamics [21] and the visible and near-IR by Schott Glass [22] are self-consistent and agree well with index data for low-absorption natural spinel [18].

Spinel refractive-index data for the visible and IR transparent region are summarized with a Sellmeier formula of the form

$$n^2-1=\frac{18.96\times 10^9}{(100,080)^2-\nu^2}+\frac{1.2234\times 10^6}{(527.18)^2-\nu^2}, \tag{1}$$

where ν is the frequency in wave numbers. This formula is applicable to bulk crystalline (or polycrystalline) stoichiometric spinel with low impurity and defect concentration and is accurate to ± 0.001. Figure 1 compares the

index-of-refraction data from several sources to Eq 1. Evaporated thin films made with spinel material have a wide index-of-refraction variation and nonstoichiometric composition [23].

Absorption in the transparent region (0.25–5 μm) is governed by impurities and defects. The structure and visible optical absorption of spinel with various amounts of chromium, cobalt, and iron have been widely studied [24–27]. Optical effects of X-ray, γ-ray [28, 29], electron [16], and neutron [16, 30] irradiation are well-known. An F center at 5.3 eV (234 nm), an F^+ center at 4.75 eV (261 nm), and a V center at 3.2 eV (387 nm) are known [16, 31]. The most prominent IR absorption feature is the OH^- absorption band that occurs at 3345 cm^{-1} [9, 15, 19, 32]. Nonstoichiometric spinel has an additional OH^- absorption band at 3528 cm^{-1} that grows with increasing alumina content [3, 9, 15, 19, 32].

The dominant loss mechanism in the visible and near-IR transparent region of polycrystalline spinel is scatter. Bulk scatter in polycrystalline spinel is low and decreases with increasing wavelength [2].

Absorption at the IR edge of transparency is dominated by multiphonon absorption. A model of multiphonon absorption for spinel has been developed and validated with experimental data over a wide temperature range [33]. The fundamental (one-phonon) lattice vibrations occur in the 300–800 cm^{-1} spectral region. Group theory predicts the following phonon modes for spinel [34–36]:

$$\Gamma = A_{1g} + E_g + F_{1g} + 3F_{2g} + 2A_{2u} + 2E_u + 4F_{1u} + 2F_{2u}. \quad (2)$$

The Raman-active modes are A_{1g}, E_g, and F_{2g}, and the F_{1u} modes are IR-active. Table I lists locations of the IR modes (transverse optical frequency) observed by several researchers [37–39]. There is good agreement on the location of three prominent modes; the fourth mode is either weak or masked by the other three. Also, other weak modes not predicted by group theory may be present because of disorder or lack of stoichiometry [35]. In particular, an absorption peak near 818 cm^{-1} becomes prominent as the alumina concentration is increased, as demonstrated by Hafner and Laves [8] and Wang and Zanzucchi [40]. Table II gives mode locations, widths, and strengths as determined by Thomas [39]. Temperature dependence of these modes has been measured over the range 290–775 K.

Table II also lists both the transverse and longitudinal optical frequencies of spinel. The transverse optical frequencies are the mode locations; the maximum longitudinal is an important parameter in the multiphonon model [33], since it designates the maximum phonon frequency.

At frequencies below the lowest fundamental optical mode, absorption decreases and the material becomes transparent. The magnitude of absorption is thought to be a combination of contributions from both the tail of

the fundamental lattice vibrations and various multiphonon difference bands. The index of refraction now also includes the effect of lattice vibrations.

The low-frequency real index of refraction (dielectric constant $\approx n^2$) of spinel was measured by Wang and Zanzucchi [40], Westphal and Iglesias [41], Stead and Simonis [42], and Ho [43]. These values lie between 2.88 and 2.90, which are slightly higher that the value of 2.86 determined from Table II. Wang [3] reported very little change in dielectric constant when m ranged from 1 to 3. Temperature dependence of the low-frequency index of refraction is given by Westphal and Iglesias [41] as 2.5×10^{-4}/K (average, 25–455 °C) and by Ho [43] as 2.3×10^{-4}/K (average, 23–300 °C), 2.8×10^{-4}/K (average, 23–1000 °C), and 3.0×10^{-4}/K (average, 23–1200 °C). Stead and Simonis [42] also give values for the imaginary index of refraction (k) in the 5–15 cm^{-1} region. Estimates of the imaginary index of refraction made from the low-frequency side (red wing) of the fundamental modes (Table II) are about 72% of the experimental value determined by Stead and Simonis [42] at 5 cm^{-1}, with better agreement at higher frequency.

Table III was constructed from measurements reported in the literature as well as model predictions. Real-index (n) data in the visible and near IR are taken from the measurements of Furutani [21] and Scheller [22].

Lattice-vibration-model results [39] are used to calculate real-index data from 0–9600 cm^{-1} and imaginary index data from 5–5000 cm^{-1}. Laser calorimetry results for k at 2.9 and 3.9 μm by Detrio and Greason [44] give extrinsic measurements of the imaginary part of the index of refraction, based on thin samples with the lowest absorption coefficients. Of particular note is the imaginary index of refraction at 2.9 μm, which lies on the OH^- absorption feature of spinel.

Measurements of Stead and Simonis [42] and others [40, 41, 43] are used to represent the low-frequency characteristics of spinel. In this region, one-phonon-model contributions [39] to k are 70 to 100% of measured values [42], and index predictions are 0.7 to 1.5% low compared with measured values [40–43]. Two- and three-phonon difference bands presumably account for the unaccounted portion of k.

The accuracy of available index data is unknown. In all data, the uncertainty in the values is probably in the least-significant digit reported in Table III. In spectral regions where several sources of data exist, there is a large disparity between references.

Figure 2 shows a composite of the complex index of refraction based on the data of Table III.

Table IV gives temperature dependence for the real part of the index of refraction. Measurements of dn/dT by Vadem *et al.* [20], Westphal and Iglesias [41], and Ho [43] are included.

Temperature-dependent absorption computed from optical models of

spinel [39] has been used to estimate total hemispherical emissivity of pure, transparent spinel over the range 200–1000 K, where the models are expected to give the best results, and defect absorption is believed to be insignificant. These results were obtained by estimating the complex refractive index at a given temperature, calculating directional emittance for a specific slab thickness, integrating over angle, and convolving the resulting spectral hemispherical emittances with the Planck function.

Table V gives the resulting total hemispherical emittance for semi-infinite slabs as a function of slab thickness. Since total hemispherical emissivity is an important function for radiation-relief calculations and may be needed to correct property measurements such as thermal conductivity, we have included this calculated result.

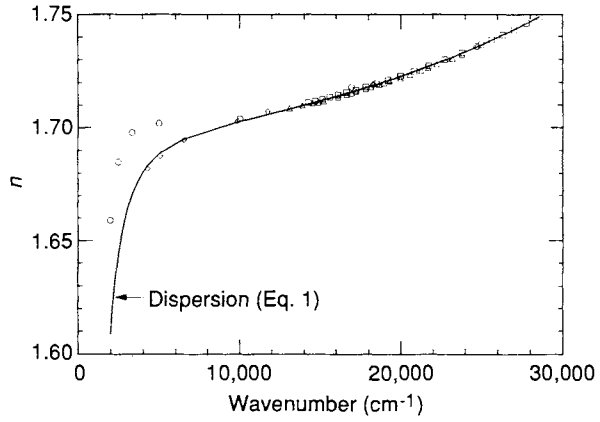

Fig. 1. Index of refraction (n) versus wave number in cm^{-1} for magnesium aluminum spinel. Data from Schlossmacher [18] (triangles), Furutani [21] (squares), Scheller [22] (diamonds), and Roy and Hastert [2] (circles) are compared with the dispersion equation (solid line) given in the text.

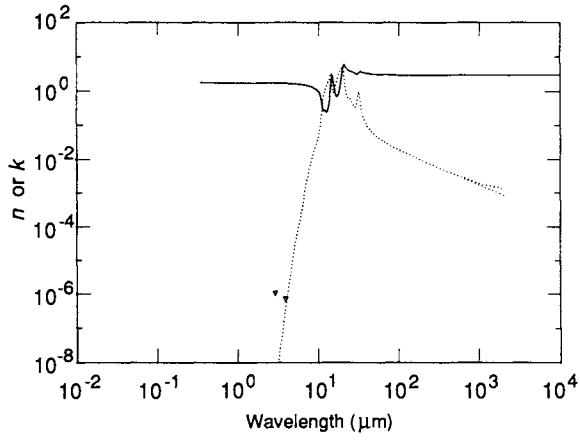

Fig. 2. Log–log plot of n (solid line) and k (dashed line) versus wavelength in micrometers for magnesium aluminum spinel. Data from various sources sometimes do not join together in overlap regions. Symbols are laser-colarimetry measurements of k.

TABLE I

Determination of Spinel Infrared Lattice-Vibration Frequencies (cm^{-1})[a]

O'Horo *et al.* [37]	Striefer [38]				Thomas [39]
	4-pole fits				
4-pole fit	#1	#2	#3	6-pole fit	7-pole fit
305	305	305	306	306	307
428(w)		416*(s)		363	400*
485(s)	490(s)	491(s)	490(s)	491(s)	482(s)
					505
	580(w)			581(w)	580*
670	670	676	674	674	675
			812(w)	812(w)	815(w)

[a]References are indicated in brackets. Letters in parentheses indicate mode strength: s = strong, w = weak. Asterisks indicate very broad modes (probably made of many modes and caused by defects). Modes at 305–308, 482–491, and 670–675 are three of the four spinel fundamental lattice vibrations. The mode at 812–815 is likely caused by nonstoichiometry (see [40]). O'Horo *et al.* [37] give the following Raman-active mode locations: 311, 492, 611 (F_{2g}); 410 (E_g); and 772 (A_{1g}).

TABLE II

Fundamental Infrared Lattice-Vibration Parameters of Spinel[a]

Mode	Transverse optical frequency (cm^{-1})	Strength	Normalized width	Longitudinal optical frequency (cm^{-1})	Refs.
1*	307	0.45	0.080	311	[37-39]
2	400	0.50	0.20	—	[39]
3*	482	2.70	0.065	497	[37-39]
4	505	0.80	0.080	—	[39]
5	580	0.15	0.30	603	[38,39]
6*	675	0.66	0.045	800	[37-39]
7	815	0.01	0.065	869	[38,39]
		Total = 5.27			

[a]The transverse optical frequency (ν_j) is the location of the mode. Modes marked with an asterisk are three of the four fundamental IR modes (F_{1u}). Frequently, one mode of greater strength (e.g., 3.5) is substituted for our modes 3 and 4 [36-38]. Preudhomme and Tarte [36] identified mode 5 as the fourth fundamental IR vibration by analogy to other spinels. The strength ($\Delta\epsilon_j$) is the contribution of the mode to the dielectric constant. The normalized width (γ_j) is the mode width divided by the mode frequency. The complex dielectric constant (ϵ) is then modeled as a function of frequency (ν) by

$$\epsilon(\nu) = \epsilon_\infty + \sum_j \frac{\Delta\epsilon_j \nu_j^2}{\nu_j^2 - \nu^2 + i\gamma_j \nu_j \nu} ,$$

where the ϵ_∞ term (= 2.892) represents the electronic contributions to the dielectric constant (plus one). This model has a static dielectric constant of 8.16.

Magnesium Fluoride (MgF_2)

THOMAS M. COTTER, MICHAEL E. THOMAS,
and WILLIAM J. TROPF
Applied Physics Laboratory
The Johns Hopkins University
Laurel, Maryland

Magnesium fluoride is a tetragonal material with TiO_2 (rutile) structure. The space group is D_{4h}^{14} or $P4_2/mnm$. The unit cell contains two formula units (six atoms). Dimensions of the cell (at 27 °C) are 0.4623 nm along the a axis and 0.3052 nm along the c axis [1, also see 2]. Theoretical density is 3.177 g/cm^3 and melting point is 1528 ± 3 K [2]. A melting point of 1543 K is also reported [3].

Magnesium ions occupy octahedral sites with D_{2h} point symmetry. Six fluorine ions at sites with C_{2v} symmetry surround each magnesium ion. Fluorine-ion positions in the unit cell are known from X-ray diffraction measurements [1, 2].

A wide transparency range from 0.12 to 8 μm [2], good mechanical properties, and low optical index of refraction make magnesium fluoride a desirable material for coatings and interference filters. MgF_2 is a positive uniaxial material, with its highest birefringence in the UV. Except for lithium fluoride, MgF_2 has the shortest wavelength cutoff of any common optical material.

Magnesium fluoride occurs naturally as the mineral selliate [3]. Single-crystal MgF_2 [3, 4] is widely used for windows, lenses, polarizers, and other optical components. Optical-quality, hot-pressed polycrystalline MgF_2 is also used for optical components, particularly in the infrared. IRTRAN 1 [5] is a trade name for hot-pressed MgF_2 made by Kodak; KO-1 is an equivalent Soviet material [6]. Olsen and McBride [7] compare properties of IRTRAN 1 and single-crystal magnesium fluoride.

MgF_2 has been used as a divalent-ion host material for solid-state lasers. Vanadium, nickel, and cobalt have been used as dopants to produce tunable solid-state lasers in the infrared [8, 9].

The UV and IR transparency of magnesium fluoride lends itself to many applications. MgF_2 has been used as a window material for UV detectors in space applications [10, 11]. The birefringence is used to polarize light in the UV [12–14]. One such polarizer, operating from the UV to the IR, has

ISBN 0-12-544422-2

been constructed [15]. The low index of MgF_2 in the IR led to its use as a Soleil compensator in the IR [16]. Magnesium fluoride is also used as a thin film to coat aluminum mirrors for enhanced reflectivity in the vacuum UV [17, 18]. Because of the relatively low index, magnesium fluoride is also used as an antireflection coating for lenses and as a low-index layer in dielectric interference filters.

Magnesium fluoride has a band gap of approximately 11.8 eV. Optical constants from the UV through the XUV have been measured for single-crystal magnesium fluoride [19–22]. The lowest-energy electronic feature of the magnesium fluoride spectrum is an exciton peak centered near 11.8 eV [20, 21]. This is due to an exciton peak at 11.6 eV for the extraordinary component and at 12.2 eV for the ordinary component [22]. The exciton peak obscures the UV absorption edge in this region, measured at 10.9 eV [20]. Although an absorption band beginning at 1320 Å has been observed, the transmission does not drop significantly until 1150 Å (10.8 eV) [2], which is close to the measured absorption edge. The interband transitions begin near 12.2 eV [21], at 12.4 eV for the extraordinary and 12.6 eV for the ordinary ray [22]. The extraordinary-ray absorption curve has structure at 18.6 eV and the ordinary ray at 15 and 20.5 eV [22]. Broad absorption structure near 20.8 eV is attributed to interband transitions [20]. These transitions are believed to arise from transitions from the upper valence band of fluorine ($2p^6$) to the conduction band of magnesium ($3s+3p$) [21]. A peak at 24.5 eV is attributed to a plasmon [20, 21]. The plasmon peak is composed of an extraordinary-ray component at 24.3 eV and an ordinary-ray component at 24.6 eV [22]. Structure seen in the absorption coefficient from 27–40 eV is attributed to interband transitions $2s^2$ level of the fluorine ion to the conduction band [19, 21]. In the 40–56 eV region, two absorption peaks exist: an absorption peak at 47.5 eV caused by a double plasmon and a peak at 54.6 eV attributed to an exciton [19]. Structure from 56–62 eV is attributed to transitions of $2p^6$ electrons of magnesium to the conduction band [19].

Refractive-index data for the MgF_2 transparent region from the UV through the IR are given by many sources [2, 12, 23–27]. Dodge [27] fitted index data (at 19°C) to a Sellmeier-type dispersion relationship of the form

$$n_o^2 - 1 = \frac{2.5903553 \times 10^{10}}{(230,499.30)^2 - \nu^2} + \frac{4.4543708 \times 10^9}{(105,692.13)^2 - \nu^2} + \frac{4.0838897 \times 10^5}{(420.28101)^2 - \nu^2} \tag{1a}$$

and

$$n_e^2 - 1 = \frac{3.0458725 \times 10^{10}}{(271,424.78)^2 - \nu^2} + \frac{6.1300694 \times 10^9}{(110,178.73)^2 - \nu^2} + \frac{4.4070997 \times 10^5}{(420.66305)^2 - \nu^2}, \tag{1b}$$

where ν is the frequency in wave numbers. Equation 1 represents electro-

nic resonances with the first two terms and all IR resonances with the third term. These terms fall in the middle of the measured electronic transitions and lattice vibrations, respectively. The overall accuracy of index calculated from Eq. 1 is quoted as better than 2×10^{-5} over the 1400–50,000 cm^{-1} range.

Change in the index of refraction with temperature, pressure, and stress is available. Thermo-optic data are given by many sources [2, 28–30] without good agreement; data from the National Bureau of Standards [28] are considered comprehensive, cover a wide temperature range, and agree well with recent measurements of the temperature dependence of optical dispersion [30]. The elastic properties of MgF_2 have been reported in the form of elastic constants, photoelastic constants, and piezoelectric constants [31, 32].

Optical properties of thin films of magnesium fluoride have been studied extensively. Much disparity exists between published data due to variations of the conditions and method of preparation of the sample under study [33–37]. In addition, thin-film properties usually do not match single-crystal properties [19, 20]. Consequently, this article concentrates on properties of single crystals.

Radiation damage of MgF_2 is described elsewhere [38]. Studies of radiation effects on the absorption of magnesium fluoride have revealed absorption bands in the UV. Three prominent absorption peaks at 117, 260, and 370 nm develop, which can be attributed to the creation of *F* centers by radiation [38]. No observations of IR absorption due to radiation have been reported [38]. The characterization of the fluorescence of MgF_2 has also been undertaken [38, 39].

Absorption at the IR edge of transparency is dominated by multiphonon absorption [40]. A model of multiphonon absorption [41] has been developed and confirmed with experimental data over a wide temperature range. Model constants for the ordinary ray of MgF_2 are given by Thomas and Joseph [42].

The fundamental (one-phonon) lattice vibrations occur in the 250–625 cm^{-1} spectral region. Group theory predicts the following phonon modes for MgF_2 [43–46]:

$$\Gamma = A_{1g} + A_{2g} + A_{2u} + B_{1g} + B_{2g} + 2B_{1u} + E_g + 3E_u, \tag{2}$$

where the A_{2g} and B_{1u} modes are optically inactive, the A_{2u} ($\mathbf{E}\|c$) and E_u ($\mathbf{E}\perp c$) modes are IR-active, and the remaining modes are Raman-active. Table I lists the IR modes as determined by Barker [44], Thomas and Joseph [42], and Giordano and Benoit [46]. Locations of the Raman modes are given by Porto *et al.* [45] as 92 (B_{1g}), 295 (E_g), 410 (A_{1g}), and 515 (B_{2g}) cm^{-1}.

Table I also lists both the transverse and longitudinal optical frequen-

cies. The transverse optical frequencies are the mode locations; the maximum longitudinal-mode frequency is an important parameter in the multiphonon-absorption model [41], since it designates the maximum phonon frequency.

At frequencies below the lowest-frequency transverse optical mode, absorption decreases and the material becomes transparent. The magnitude of absorption is thought to be a combination of contributions from both the tail of the fundamental lattice vibrations and various multiphonon difference bands. The index of refraction now also includes the effect of lattice vibrations. Estimates of low-frequency absorption made from the red wing of the fundamental modes (Table I) for MgF_2 are about 60% of the ordinary-ray imaginary index of refraction and 95% of the extraordinary-ray values determined by Bystrov *et al.* [47] in the 10–23 cm^{-1} region. Measurements of two different sintered samples of polycrystalline MgF_2 by Stead and Simonis [48] showed yet higher absorption.

The low-frequency index of refraction of magnesium fluoride is given by Fontanella *et al.* [49] at 1000 Hz and by Bystrov *et al.* [47] for the 300–700 GHz range. These data agree with each other and with the data in Table I except for the slightly higher extraordinary-ray value given by Fontanella *et al.* [49]. No temperature-dependent low-frequency index data were found, but pressure dependence is given by Link *et al.* [50].

Table II was constructed from measurements reported in the literature as well as model predictions [51]. Real-index data (n) from 10–83 eV and imaginary-index (k) data from 11–83 eV are taken from several sources [19–22]. The measurements by Hanson *et al.* [19], Williams *et al.* [20], and Stephan *et al.* [21] did not distinguish between ordinary- and extraordinary-ray components. These data can be considered to be an "average" for the crystal. Thomas *et al.*'s [22] measurement of ordinary- and extraordinary-ray optical constants for the 11–28 eV region are also included.

Ordinary-ray index data in the 0.115–0.200 μm region are taken from Williams and Arakawa [23], supplemented by measurements of Steinmetz *et al.* [12]. Extraordinary-ray data for this region are obtained by combining ordinary-ray data with the anomalous dispersion data of Chandrasekharan and Damany [24]. Both ordinary- and extraordinary-ray data in the 1400–50,000 cm^{-1} range are calculated from the Sellmeier dispersion relationships (Eq. 1) of Dodge [27]. One value of ordinary-ray absorption coefficient is given by Steinmetz *et al.* [12].

Single [51] and multiphonon [41] lattice-vibration models are used to estimate the complex index of refraction for wavelengths of 7.41 μm and longer. Measurements of Bystrov *et al.* [47], and Fontanella *et al.* [49] are the best available low-frequency index data.

The accuracy of index measurements in the electronic region is relatively poor; estimated errors are approximately 10%. Data from Hanson *et al.*

[19] and Williams *et al.* [20] agree well in the overlap region (20–27 eV). Data from Stephan *et al.* [21] have consistently lower n and higher k compared with other sources [19, 20]. Data from Thomas *et al.* [22] have precision on the order of ±5%.

The real-index data from 0.115–0.200 μm have a quoted accuracy of ±0.002; the dispersion formula of Dodge [27] represents the data from 0.2–7.0 μm within ±0.00002. The accuracy of complex-index data at longer wavelength is unknown, but uncertainty in the values is probably in the least-significant digit reported in Table II (that is, n accurate to ±0.01 and k to about 5%). Low-frequency real-index measurements of Fontanella *et al.* [49] are given an accuracy of ±0.001. Bystrov *et al.* [47] states the accuracy of n to be ±0.005 and k to be within ±5%.

Figures 1 and 2 show a composite of the complex index of refraction based on the data of Table II. Figure 1 gives the ordinary-ray index and Fig. 2 shows the extraordinary-ray properties. Complex index-of-refraction data for the electronic region (wavelengths below 0.05 μm) derived from unpolarized measurements with an unknown mix of ordinary- and extraordinary-ray index are included in Fig. 1.

Tables III and IV give temperature dependence for the real part of the index of refraction. Measurements of dn/dT by Feldman *et al.* [28] typically have a standard deviation to a linear temperature-dependence fit of 0.1×10^{-6}/K.

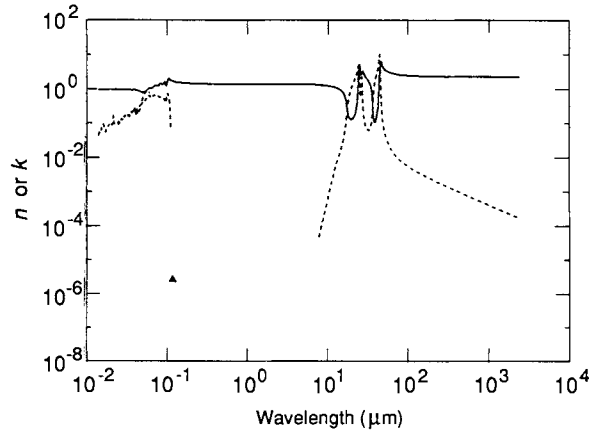

Fig. 1. Log–log plot of n_o (solid line) and k_o (dashed line) versus wavelength in micrometers for the ordinary ray of magnesium fluoride. Data below 0.05 μm (electronic region) are combined ordinary- and extraordinary-ray results.

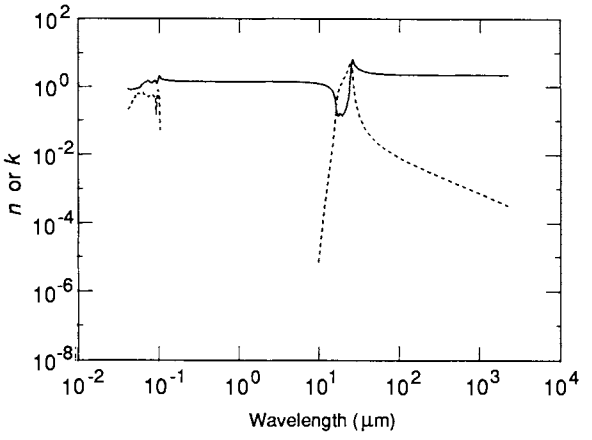

Fig. 2. Log–log plot of n_e (solid line) and k_e (dashed line) versus wavelength in micrometers for the extraordinary ray of magnesium fluoride.

TABLE I

Fundamental Infrared Lattice Vibration Parameters for MgF_2[a]

Mode	Transverse optical frequency (cm^{-1})	Strength	Normalized width	Longitudinal optical frequency (cm^{-1})	Refs.
		E ⊥ c axis (ordinary ray)			
1	247	2.22	0.014	303	[44]
2	410	0.19	0.033	415	[44]
3	450	1.14	0.058	617	[44]
	Total = 3.55				
1	248	2.23	0.0115	302	[51]
2	408.5	0.22	0.0165	414	[51]
3	447	1.10	0.025	621	[51]
4[b]	535	0.05	0.3		[51]
	Total = 3.60				
1	251			304	[46]
2	413			422	[46]
3	452			610	[46]
	Total = 3.38				
		E ∥ c axis (extraordinary ray)			
1	399	2.7	0.048	625	[44]
2[c]	556	0.01	0.08		
	Total = 2.71				
1	404	2.69		626	[46]

[a]The frequency (ν_j) is the location of the mode (transverse optical frequency). The strength ($\Delta\epsilon_j$) is the contribution of the mode to the dielectric constant. The normalized width (γ_j) is the mode width divided by the mode frequency. The complex dielectric constant (ϵ) is then modeled as a function of frequency (ν) by:

$$\epsilon(\nu) = \epsilon_\infty + \sum_j \frac{\Delta\epsilon_j \, \nu_j^2}{\nu_j^2 - \nu^2 + i\gamma_j \nu_j \nu} ,$$

where the ϵ_∞ term (= 1.886 for E ⊥ c and 1.918 for E ∥ c axis) represents the electronic contributions to the dielectric constant (plus one).

[b]Mode 4 (E ⊥ c) is probably caused by an impurity.

[c]Barker [44] identifies this as a weak forbidden mode.

TABLE II

Values of n and k Obtained from Various References for Magnesium Fluoride[a]

Magnesium Oxide (MgO)

DAVID M. ROESSLER
General Motors Research Laboratories
Warren, Michigan
and
DONALD R. HUFFMAN
Physics Department
University of Arizona
Tucson, Arizona

Magnesium oxide is an ionic material, crystallizing in the rock-salt structure and cleaving on (100) and (111) planes. It is found in nature as periclase or β-magnesia. MgO has a molecular weight of 40.32, a density of 3.576 kg/m^3 at 25°C, and a lattice parameter of 4.215 Å. It is insoluble in water but atmospheric moisture reacts with the surface to form a thin film, which can be easily polished off. High physical strength and stability, a melting point near 2852°C, and excellent optical transparency (absorption coefficient less than 1 cm^{-1}) throughout the range 0.25 to 6.8 μm, combine to make the material of considerable interest.

Very pure, microcrystalline powders can be prepared in several ways and exhibit high (over 90%) diffuse reflectance throughout the visible region and extending into both the ultraviolet (UV) and infrared (IR). As such, they have been of interest as reference standards in optical work and as coatings in devices such as integrating spheres. Similar optical properties are exhibited by "smoked" or "fumed" MgO, produced by burning magnesium ribbon and collecting the smoke on a substrate. However, pressed, sintered material can be made to have optical properties close to those of the single crystal. It has been used for a variety of optical purposes, particularly as window and substrate material.

In the mid-1970s, one of us [1] presented a composite picture of the dielectric parameters, ε_1 and ε_2, of MgO in the range 0.02 to 28 eV. The present review includes more recent data, extends the spectral range, and focuses on the n and k values (Table I and Fig. 1).

X-Ray and Ultraviolet Range

The only quantitative data published on the optical properties of MgO at photon energies above about 120 eV appear to be those of Maeda *et al.* [2],

in the range 500 to 590 eV. Using bremsstrahlung radiation from a tungsten target, in conjunction with an X-ray spectrometer, they were able to measure the transmission of MgO films deposited onto 350 nm-thick aluminum foil. From the spectra of films with thicknesses of 50 nm and 200 nm, they derived the absorption coefficient in the region of the oxygen K absorption edge. The absorption increases sharply near 535 eV, from a background level of about 5×10^3 cm^{-1} to a maximum value of 7×10^4 cm^{-1} at 539 eV. There are several smaller peaks to higher energies. Photoelectric-yield spectra [3] measured on powdered MgO show similar structure. The tabulated values of k (Table I) in the range 500 to 590 eV have been calculated from the absorption-coefficient data of Maeda *et al.* [2]. The data scatter indicates an uncertainty of at least $\pm 10\%$.

The region 30 to 100 eV has been explored more extensively. Townsend [4] explored the Mg $L_{2,3}$ edge in MgO, which occurs near 55 eV. He oxidized magnesium foils and measured their opacity in the range 80 to 350 Å, using a concave grating spectrograph and a spark-discharge light source. He assumed that the densities of the foils were the same as that of the bulk materials, in order to estimate the thickness of the MgO film. Taking his value of 171 nm for the thickness of one sample, we can calculate k from the opacity data. The resulting k values increase from less than 0.015 at a wavelength of 100 Å to about 0.06 at 320 Å. Superimposed on this background is the structure associated with the Mg L edges.

Fomichev *et al.* [5] used an X-ray spectrometer with a diffraction grating to examine the absorption spectra of MgO layers of unknown thickness. The material was prepared by burning magnesium in air and depositing the product onto a nitrocellulose substrate. Absorption data are shown on an arbitrary intensity scale in the range 50 to 68 eV but show the L edge structure, similar to that in Townsend's work. They were also able to measure the K absorption of oxygen, just above 535 eV. Their data, in arbitrary intensity units, cover the range 535 to 570 eV, and show similar features to those studied later in more detail by Maeda *et al.* [2]. The earlier work [5] is not quite as well resolved or sophisticated, and the absorption peaks are systematically displaced to higher energies by about 5 eV. A follow-up paper [6] presented more extensive data for the 35 to 100 eV region. In neither paper [5, 6] is film thickness quoted.

Although only optical density data are available in the literature for the range 80 to 120 eV, there are k data at lower energies. Further, in the overlap region below 80 eV, the primary spectral structure in both Townsend's data [4] and in those of Fomichev and Zhukova [6] replicates that in the work on single crystals to be described later. There are small displacements in peak energies, but the general agreement is good enough for us to calibrate the optical-density data and derive equivalent k values. We have therefore normalized both sets of optical-density data to give k values in agreement with the lower energy data, and used the resultant

values above 80 eV in Table I. The uncertainty in k is high, over $\pm 50\%$, because the MgO samples were prepared from burning magnesium rather than in the form of single crystals.

Hanson [7] was able to measure the optical properties of single crystals in the range 29 to 80 eV and provide quantitative data for both n and k. He used a high-voltage capillary discharge in air to provide a line-emission source. He then measured the reflectance of single-crystal MgO and the transmittance of amorphous thin films. The single crystals were cleaved along the (100) plane immediately before they were transferred to the vacuum chamber. Data were recorded for 12 angles of incidence in the range 20 to 75° and used to determine n and k from a least-squares fit to the Fresnel equations. However, data scatter, particularly in k, was rather large. The data were therefore used in conjunction with a Kramers–Kronig (K–K) analysis of 15° incidence reflectance data to provide final values. Transmittance data on two films, about 28 nm and 78 nm thick, respectively, were also used to derive k values.

As noted previously, the data published by Hanson and his coworkers [7, 8] show structural features similar to those of Townsend [4] and Fomichev *et al.* [5, 6], including the Mg L edge. The k values for his thin films are about a factor of two greater than those of Townsend, rising from 0.04 at 72 eV to about 0.12 at 29 eV. The single-crystal data for k show considerable scatter but are generally larger than those for the thin films. Values at 72 eV are in the range 0.06 to 0.1; at 29 eV, the values are in the range 0.17 to 0.25. The n values for the single crystal [8] show much less scatter. They are relatively flat, staying within the values 0.91 to 0.99 throughout the range 29 to 80 eV.

There are several sources of reflectance data on single-crystal MgO in the range 7 to 30 eV. Combining the best of these with the reflectance data of Hanson *et al.* [8] gives us a continuous spectrum for the range 6 to 72 eV. We can then use a K–K analysis to compute the corresponding values of n and k. Some of the published data are only on a relative reflectance scale, but there is general agreement regarding the primary spectral features. However, there are substantial variations in the absolute magnitude of the reflectance, especially in the 7.6 eV exciton region. The published data on the optical constants show corresponding variations, and we must therefore consider what reflectance data to use as a primary source for n and k.

Nelson [9] measured the relative reflectance of a cleaved, single crystal obtained from the Norton Research Corporation (Canada), Ltd., Niagara Falls, Ontario, in the wavelength range 90 to 175 nm. He observed three peaks: the one at 164 nm narrowed in measurements at 140 K, whereas the broad structure near 115 nm and the peak at 93 nm seemed to be temperature-insensitive. At room temperature, the three structures had comparable reflectance; at 140 K, the longest wavelength peak, assumed to be excitonic, was higher. Nelson believed that the absorption coefficient

for the exciton was of the order of 10^6 cm^{-1}. The value of k would therefore be of the order of unity.

Reiling and Hensley [10] measured the relative reflectance of freshly cleaved surfaces of several single crystals at 45° incidence, and the absorption of both thin cleaved samples and films evaporated onto LiF substrates. The main features resemble those in Nelson's data [9], the biggest difference being a sharp drop in reflectance on the high-energy side of the exciton peak. Some single crystals grown in their own University of Missouri laboratory showed both the sharpest exciton peak in reflection, and also the lowest absorption on the low-energy tail of this peak. The absorption coefficient was between 30 and 50 cm^{-1} throughout the range 5.8 to 7.0 eV for this material, whereas other crystals (Norton) had absorption coefficients of about 75 cm^{-1} at 5.8 eV, increasing to about 285 cm^{-1} at 7.0 eV. The k value for the Missouri material is about 5×10^{-5} from 5.8 eV to nearly 7 eV, even though there was some evidence of extrinsic structure in both the reflection and absorption low-energy tails of the exciton peak. The intrinsic absorption increased very rapidly beyond about 7.4 eV, being well above 500 cm^{-1} at 7.5 eV for all crystals examined (at room temperature).

Harris [11] was able to measure the absolute reflectance of MgO in the ultraviolet. He used a hydrogen discharge tube for a light source. This provides a strong continuum at energies below 7.5 eV and line emission at higher energies. A vertically mounted, rotatable, phosphor-coated light pipe coupled to a blue-sensitive photomultiplier enabled absolute measurements to be made. Roessler [12], using the same equipment, extended these data, made measurements at both 15° and 45° incidence, and also used the K–K relations to derive the dielectric parameters. The near-normal-incidence data in the range 4 to 14 eV show structure very similar to those of Reiling and Hensley [10] and Nelson [9]. The room-temperature reflectance at the exciton peak was over 22% and dropped sharply to just under 11% on the high-energy side (near 8 eV). The broad peak near 11 eV had a reflectance of about 17%, while the peak just above 13 eV had a reflectance of about 23%.

Roessler and Walker [13] made studies of the exciton reflectance at both room temperature and at 77 K. The crystal was cleaved in air but transferred to a vacuum system of the reflectometer within about two minutes. At 300 K, the exciton peak had a reflectance of about 25% at 7.60 eV, whereas crystal surfaces exposed to laboratory air for three days showed reflectances of 20–23%. Data on the best surface were reproducible to within 2% while the sample was maintained in the vacuum system. At 77 K, the exciton structure exhibits two peaks at 7.69 and 7.76 eV. Later, Whited and Walker [14] showed that additional structure can be seen at 25 K, reflectance peaks occurring at 7.689, 7.715, 7.752, and 7.768 eV.

Studies [15] over a more extended range (4 to 12 eV) confirmed earlier

findings that only the exciton structure showed strong temperature dependence, whereas the reflectance in the region 8 to 12 eV was virtually unchanged between room temperature and 77 K. It was again noted that surfaces exposed for several days to laboratory air deteriorated, as indicated by lowering of the exciton reflection peak and a slight broadening of the spectral features. The best surfaces had peak reflectances of about 27.5% at 7.6 eV, 23% at 11 eV, and 31.5% at 13.5 eV (all at room temperature).

Roessler and Walker [16] used a pulsed discharge in argon to provide line emission beyond the hydrogen-discharge limit, and were able to extend their reflectance data to 28 eV. A very broad composite structure was seen in the 16 to 23 eV region, peak reflectances being about 25%. The data were recorded at 8° incidence and repeated on several freshly cleaved, single-crystal samples (all from Semi-Elements, Inc., Saxonburg, Pennsylvania). Light-source emission lines exhibiting intensity fluctuations of more than 5% were not used in the final computation of the reflectance. A K–K inversion was used to generate n and k values from these reflectance data [17].

Williams and Arakawa [18] also measured the reflectance of cleaved, single crystals of MgO in the same energy range. Their samples were obtained from Muscle Shoals Minerals Company, Barton, Alabama, and from J. Burrow of Bristol University, U.K., and were cleaved in the (100) plane. They contained from 10 to 57 ppm of Fe. The data were recorded at 15° incidence and qualitatively very closely resemble the Roessler and Walker data [16] in spectral structure. However, the absolute reflectance was slightly less: their exciton-peak reflectance was only 22%, the 11 eV peak had a reflectance of 19%, the 13.5 eV peak had a reflectance of 27%, and the broad structure near 20 eV had maximum values near 20%. Thus, the peaks were about 0.04 to 0.05 lower in absolute reflectance than those of Roessler and Walker. Williams and Arakawa noted that there were variations in absolute reflectance between their own samples. They also used the K–K relation to compute n and k values from the reflectance.

Freehouf [19] measured the reflectance of a single-crystal sample of MgO over the range 4 to 30 eV, using synchrotron radiation. Data were recorded for sample temperatures in the range 100 to 400 K. The sample was cleaved in air just prior to being mounted in the vacuum system. Measurements were also made on a polished sample and showed considerable broadening of the exciton structure near 7.5 eV, but little difference at higher energies. He estimated the absolute values of reflectance to be correct to ± 0.03. The room-temperature data have almost identical structure to that revealed by the earlier work [16, 18], and the absolute magnitudes lie between the two previous sets of data over this range. These data are of particular interest because of the use of a continuum rather than a line source. In principle, this should provide more reliable details of

optical structure, especially above 20 eV, where there are often gaps of up to 0.5 eV between emission lines. Freehouf also used a K–K inversion of the reflectance to compute the optical constants, but shows the ε_2 data only at 100 K.

Mikhailin *et al.* [20] measured the relative reflectance at 15° incidence of cleaved single crystals in the range 15 to 40 eV, using the DESY synchrotron light source. There were only minor differences from earlier data, mainly in the 20 eV structure. Kuusmann and Fel'dbakh [21] measured the relative reflectance in the exciton region at 10 K, and saw fine structure similar to that observed in the 25 K data of Whited and Walker [14]. French and Coble [22] made preliminary measurements of the room-temperature reflectance of MgO in the range 7.5 to 14.5 eV. Details of the measurement, including crystal quality, were not given, but the absolute values of the reflectance are low. The exciton-peak reflectance, for example, was only 18.5%.

Summarizing the reflectance data, we find that reports of the value at the 7.6 eV exciton peak vary from as low as 18.5% to as high as 27.5%. The variations are slightly smaller at the higher-energy peaks: values for the peak near 21 eV range were from 19% to 25%. In general, we believe that the data corresponding most closely to intrinsic bulk MgO are those with the highest reflectance values and the sharpest spectral features. The exciton peak near 21 eV range from 19% to 25%. In general, we believe that the higher-energy features seem to be remarkably durable in terms of qualitative structure.

In this connection we note the results of Carden *et al.* [23] on the ion bombardment of an electropolished single crystal of magnesium. This process promotes rapid growth of an oxide layer, which can be monitored by optical reflectance measurements. They measured the reflectance in the range 8.3 to 41.3 eV, using the synchrotron radiation from the University of Wisconsin storage ring. The optical reflectance after bombardment was much lower than before in the range below 12 eV, but virtually unchanged at higher energies. The film was sufficiently like MgO to exhibit weak reflectance structure near 11 eV, 13 eV , and 20 eV, although the reflectance throughout this region was less than 4%.

The preferred reflectance data in the range 5 to 17 eV are those of Roessler and Walker [16]. They exhibit the highest and sharpest reflectance values; the low-energy tail of the exciton peak extrapolates smoothly onto values of the reflectance computed from reliable refractive-index data; and there is close agreement with the synchrotron data of Freehouf [19] in the 11 to 17 eV range. In the range 17 to 23 eV, we believe the reflectivity of single-crystal MgO is slightly lower than the Roessler and Walker data and closer to the values measured by Freehouf. The line emission from the spark discharge in argon [16] is not as stable in intensity as the light from the synchrotron source [19], and the data scatter is

significantly larger than in the hydrogen-discharge light-source range. Both sets of data [16, 19] differ by only about ±0.02 in absolute reflectance in this region, well within the estimated uncertainty. Above 23 eV, we extrapolated the reflectance to join the data of Hanson *et al.* [7, 8].

The final values of n and k used for Table I for the range 6 to 75 eV were obtained from a K–K inversion of the reflectance data selected as above. We took precautions to minimize computational errors introduced by integration of the reflectance data over a limited energy range. The low-energy tail was extrapolated smoothly to below 1 eV, using known values of the refractive index (discussed later), whereas the upper end of the spectrum was extrapolated to 800 eV on the assumption that the reflectance varied inversely with the fourth power of the energy. Further, we employed the correction technique described by Roessler [24] for dealing with K–K analysis in limited spectral regions. By varying the width of the spectral range, we estimate that our use of the K–K analysis contributes an uncertainty of less than ±0.003 to the tabulated values of n and k. However, the total uncertainty in the final values of n and k in the range 7 to 75 eV is at least ±0.05. This is primarily because the relative uncertainty in the original reflectance measurements is at least 3%. Three decimal places are used in Table I to emphasize the spectral structure in n and k rather than to denote true precision. Our present values of n and k in the range 20 to 30 eV are systematically lower than those reported by previous groups [8, 18, 19].

Several workers have measured the electron-energy-loss spectra (EELS) of MgO and compared the spectral features with those obtained optically. Venghaus [25] analyzed his 60 kV EELS spectrum with a K–K transformation and obtained the dielectric parameters, ε_1 and ε_2, in the range 0 to 80 eV. There is remarkable agreement with the optical data of Roessler and Walker [16] in the region of spectral range overlap, 5 to 28 eV. Every feature, with the obvious exception of the 7.6 eV exciton, is reproduced.

Reflection-electron-energy-loss spectra from excellent, cleaved surfaces of single-crystal MgO [26] also reproduce the optical structure in the range 5 to 28 eV. Kambe *et al.* [27] explored several spectral energy regions via EELS from MgO crystallites. Their data, in arbitrary intensity units, cover several ranges: 0 to 60 eV, showing the plasmon loss just above 20 eV; 40 to 120 eV, showing the Mg L edges; 500 to 750 eV, showing the oxygen K edge; and 1250 to 1500 eV, showing the Mg K edge. Where corresponding optical data exist, there is good agreement for the spectral structure. The EEL spectra in the region of the Mg L edges show peaks close to those seen in the optical data [4, 5, 6]; similarly, there is good agreement for the oxygen K edge [2, 5]. We do not know of any optical data in the region of the Mg K edge, but on the basis of the EEL spectra, the value of k should show a small increase above 1310 eV.

A derivation of both n and k from EELS in the range 15 to 40 eV has

been made for evaporated films of MgO [28]. The exciton structure is missing, as anticipated, and the spectra lack the fine detail of the optical data. However, there are some interesting similarities to the present values of n and k in terms of general spectral dependence, despite the differences in both material (thin film rather than bulk single crystal) and experimental probe (EELS rather than optical reflectance).

Absorption in the Near-UV through Near-IR Region

MgO has excellent transparency throughout the near UV, visible, and near IR. In good material the value of k is less than 10^{-4} throughout the wavelength region 0.17 to 7.3 μm, and less than 10^{-7} in part of this range. Impurities and other defects can significantly increase this absorption. For example, Hibben [29] did some early work on the absorption induced by UV irradiation. The present review will generally exclude discussion of extrinsic features, except insofar as the associated absorption is presumed to be greater than that of any intrinsic absorption.

Molnar and Hartman [30] reported the effect of 40 kV X-irradiation on the absorption in the 0.2 to 0.9 μm region. They induced at least three bands, with peaks at 0.22 μm, 0.285 μm, and 0.525 μm. Although they did not show the absorption of preirradiated crystals, their data can be regarded as upper bounds to the intrinsic absorption. The value of k is then less than 3×10^{-5} at 0.2 μm, less than 4×10^{-6} near 0.35 μm, and less than 10^{-6} beyond 0.85 μm. The crystals were obtained from the Norton Research Corporation (Canada) Ltd.; some were very clear, and others had a slight yellow or greenish tint. The absorption data reported were from clear samples, which, from spectrographic analysis, revealed no impurities other than about 0.1% of calcium.

Tyler and Sproull [31] measured the transmittance of three unpolished MgO crystals (Norton), in the wavelength range 0.2 to 0.4 μm. They showed comparable absorption: at 0.21 μm, the absorption coefficient was estimated to be about 15 cm^{-1} ($k = 2.5 \times 10^{-5}$), and to result partly from impurities.

Weber [32] measured the transmission of plates of MgO with thicknesses of 0.42 and 0.92 mm, which had been heated in various atmospheres of excess oxygen and excess metal. He derived the absorption coefficient in the range 1.5 to 8 eV and noted the treatment-senstive structure. For the least-absorbing samples, k was about 6.5×10^{-5} at 6.075 eV (0.204 μm), decreasing monotonically to 3.1×10^{-6} at 5.0 eV, and being too small to measure at 4.5 eV.

Johnson [33] obtained some very clear, synthetic single crystals from several sources and cleaved them to obtain plates with thicknesses of 0.27 to 0.75 mm. The purest samples, grown at the University of Missouri, contained only a few parts per million of Ca, Fe, Na, and Ni, as principal impurities. They had a blue-ultraviolet fluorescence under UV excitation,

whereas less pure samples (from Norton and from the Lamp Division of thue General Electric Company, Cleveland, Ohio (GE)) were nonluminescent. The absorption coefficient, uncorrected for surface reflection losses, was derived from transmission measurements in the range 0.16 to 0.35 μm. The GE and Missouri samples had very similar absorption; the Norton material had about twice as much absorption at wavelengths longer than 0.175 μm. All samples had absorption coefficients greater than 400 cm^{-1} at 0.16 μm. The absorption dropped to 20 cm^{-1} at 0.18 μm in the Missouri samples and to 6 cm^{-1} at 0.22 μm.

Johnson's data [33] provide the lowest values of k reported for the range 7.3 to 6.7 eV, and extrapolate smoothly to the values determined by K–K analysis at higher energies. We therefore use these in Table I.

Peria [34] examined the 3 to 6 eV UV absorption of MgO crystals from a wide variety of sources. The transmittance was measured on cleaved samples from 0.2 to 1 mm thick. Most showed extrinsic absorption features consisting of various admixtures of bands at 4.3, 4.8, and 5.7 eV. These could often be reduced if the samples were heated in vacuum. The k values in the least absorbing material decrease from about 2.5×10^{-5} at 5.8 eV to 3.3×10^{-6} at 5.1 eV, and are lower than found in any other work in the 5 to 5.5 eV range.

Ballesteros *et al.* [35, 36] recently made an extensive study of optical absorption in a variety of MgO crystals, with controlled metal impurities and subjected to various heat treatments. Absorption coefficients are given for the range 2 to 6.5 eV. The most transparent material is slightly more absorbing than that of Peria [34] below 5.5 eV but provides lower values of k at higher energies, joining smoothly onto Johnson's data [33] above 6.5 eV.

The few data that exist for k in the 2 to 5 eV range all exhibit structure indicating that extrinsic absorption is present. The most precise measurements are probably those of Harrington *et al.* [37], who used combined wavlength-modulation and laser-calorimetric techniques to measure the low absorption in the 2.4 to 3.6 eV range. The wavelength-modulation spectra give the derivative of the absorption coefficient. This is then integrated, the constant of integration being given via Ar-ion-laser calorimetric measurements at the discrete laser-line wavelengths. No details of the samples were given. The absorption coefficient decreased from about 0.3 cm^{-1} at 0.355 μm to about 0.02 cm^{-1} at 0.502 μm, the latter giving a k value of 8×10^{-8}.

A completely different technique was used by Sakhnovskii [38], who determined absorption coefficients from a detailed analysis of the diffuse reflection of powdered MgO in the range 0.24 to 1 μm. The powder was obtained by burning magnesium shavings on a steel plate, and the measurements were performed with an integrating photometer. The values of k derived from his data are within a factor of three of those derived from the

single-crystal data [32–37]. The earlier data of Molnar and Hartman [30] give values of k between five and ten times those of Sakhnovskii over the range 2 to 5 eV, but both show the same general spectral features, including a broad absorption minimum near 3 eV.

Most of the data for k that exist in the range 0.3 to 2 eV (4 to 0.6 μm) were made at discrete laser wavelengths: 1.319 μm (modified Nd:YAG), 2.7 μm (HF), and 3.8 μm (DF). There are strong impurity bands in this region, probably associated with oxygen or OH^-. Values of k derived from different sources range from about 2×10^{-8} to a few times 10^{-6}.

Harrington *et al.* [39] used standard laser-calorimetric methods and analysed their data from a single-crystal sample (Norton Company) to derive the absorption coefficients at 2.7 and 3.8 μm. They showed that the respective values of $4.0\times10^{-2}\,\mathrm{cm}^{-1}$ ($k=8.6\times10^{-7}$) and $5.4\times10^{-3}\,\mathrm{cm}^{-1}$ ($k=1.6\times10^{-7}$) indicate extrinsic absorption contributions.

Laser calorimetry was also used by Fernelius *et al.* [40] to measure the absorption of some polished Norton crystals at 1.319, 2.7, and 3.8 μm. Spectral traces indicated extrinsic absorption features in this wavelength range, and absorption measurements varied significantly with the sample at 2.7 μm. However, a sample that appeared slightly yellow-green in color was less absorbing at 2.7 μm than a very clear sample. The average value of k was 3×10^{-6}. At $\lambda=3.8$ μm, k varied from 2.8×10^{-7} to 3.2×10^{-7}. The absorption values originally reported for the 1.319 μm wavelength were revised later [41]. The k values for two samples were 7.1×10^{-8} and 9.2×10^{-8}, the tinted sample having lower absorption than the clear crystal, possibly because of its superior surface polish.

The lowest values of absorption at 2.7 and 3.8 μm were obtained by Hordvik and Skolnik [42], using a photoacoustic technique. They examined a mechanically polished MgO crystal supplied by Norton. The photoacoustic technique allows separation of the bulk and surface contributions. At 2.7 μm, the bulk absorption coefficient was $5.2\times10^{-3}\,\mathrm{cm}^{-1}$ ($k=1.1\times10^{-7}$), and the loss per surface was $9\times10^{-4}\,\mathrm{cm}^{-1}$. At 3.8 μm, the bulk value was $6.7\times10^{-4}\,\mathrm{cm}^{-1}$ ($k=2.0\times10^{-8}$), and the loss per surface was $1\times10^{-4}\,\mathrm{cm}^{-1}$. Hordvik and Skolnik also show bulk-absorption-coefficient data extending from 3.8 μm to 8.4 μm. The k values derived from these data are among those we consider most representative of intrinsic bulk material.

Infrared wavelength-modulation spectroscopy [43] of a Linde A polished single crystal of MgO from Optovac, North Brookfield, Massachusetts, shows extrinsic structure in the absorption coefficient throughout the region 2.5–5 μm. Although this changed slightly, depending on whether the sample was measured in normal laboratory air or in a dry-nitrogen atmosphere, the total absorption remained small. The data were normalized to a value of $7.6\times10^{-3}\,\mathrm{cm}^{-1}$ ($k=2.3\times10^{-7}$) at $\lambda=3.8$ μm. This results in k values of less than 3×10^{-7} throughout the range. These values

are lower than those of Hordvik and Skolnik near 5 μm and do not extrapolate as smoothly onto the available longer-wavelength data.

Refractive Index in and near the Visible Region

Early measurements of the refractive index of MgO in the visible region generally employed prisms, and were reported to three or four decimal places. References [44–49] describe some of this work, which was subsequently compiled and analyzed by Haase [50].

An extensive study was made by Strong and Brice [51], who cut two prisms from one of several very pure Norton MgO crystals and used a minimum-deviation method to measure the refractive index at 23°C in the range $\lambda = 0.2536$ μm to $\lambda = 0.7065$ μm. The corresponding values for n were quoted to four decimal places in the ultraviolet and to five decimal places in the visible region, and decreased from 1.8450 to 1.73126. Measurements were also made at 2°C and dn/dT was determined to be 1.47×10^{-5}/°C at $\lambda = 0.4861$ μm ($n = 1.74711$) and to be 1.14×10^{-5}/°C at $\lambda = 0.6563$ μm ($n = 1.73340$).

Radhakrishnan [52] found that the 23°C data of Strong and Brice could be fit to within ±0.003 over the range 0.2967 to 0.7065 μm by the formula

$$n^2 = 1.3224 + \frac{1.6294\lambda^2}{(\lambda^2 - 0.01387)}. \tag{1}$$

Peria [34] has a slightly different equation, which fits the whole spectral range with the same degree of fit.

Radhakrishnan also measured the temperature coefficient of the refractive index of a polished, strain-free crystal at the wavelengths 0.4358, 0.5461, and 0.5893 μm. He used an interferometric method from room temperature up to 400°C, and found that dn/dT decreased slightly with wavelength but did not vary with temperature. Later [53], he extended the wavelength coverage to 0.4047 μm and 0.3650 μm, confirming the trends seen earlier. His values for dn/dT decrease from 1.95×10^{-5}/°C at 0.3650 μm to 1.60×10^{-5}/°C at 0.5893 μm.

The most detailed refractive-index data for MgO are those of Stephens and Malitson at NBS [54]. Measurements were made on two prisms of magnesium oxide crystals of "excellent optical quality" by the minimum-deviation method in the wavelength range $\lambda = 0.36117$ μm to $\lambda = 5.35$ μm. In the visible region, measurements were made at temperatures near 20°C, 30°C, and 40°C, at each of nine wavelengths. These data were then averaged for the two prisms. The final values of the refractive index at 30°C were found to fit a four-constant dispersion equation:

$$n^2 = 2.957019 - 0.0101373\lambda^2 + \frac{0.0216485}{(\lambda^2 - 0.0158650)} \tag{2}$$

The computed values are within $\pm 6 \times 10^{-6}$ of the averaged, corrected values, throughout the visible region.

Stephens and Malitson fitted the 23.3°C refractive-index data for the whole wavelength range from 0.36117 to 5.35 μm to a five-constant dispersion equation:

$$n^2 = 2.956362 - 0.01062387\lambda^2 - 0.0000204968\lambda^4 + \frac{0.02195770}{(\lambda^2 - 0.01428322)}. \tag{3}$$

The values computed from this formula are systematically lower than those of Strong and Brice at the same temperature by about 3.7×10^{-4}.

Saksena and Viswanathan [55] have given a slightly different dispersion equation for the 23°C NBS data, but without improving the fit. Dodge [56] has fitted the 20 °C NBS data to the following equation:

$$n^2 = 1 + \frac{1.111033\lambda^2}{\lambda^2 - 0.005076} + \frac{0.8460085\lambda^2}{\lambda^2 - 0.018912} + \frac{7.808527\lambda^2}{\lambda^2 - 723.2345}. \tag{4}$$

More recent measurements confirm the results of Stephens and Malitson. For example, the compilation by Moses [57] includes data on a 99.7% pure single crystal (Norton) [58]. Values of n were measured at about 25 °C in the range 0.6907 to 5.35 μm and agree to five decimal places with the Stephens and Malitson values. Herzberger and Salzberg [59] measured several samples of MgO, found no significant differences from the NBS data, but provided a different dispersion equation:

$$n = 1.71960 + 0.006305L - 0.000090L^2 - 0.0031356\lambda^2 - 0.00000770\lambda^4, \tag{5}$$

where $L = 1/(\lambda^2 - 0.028)$.

They did not state the temperature: we assume it to be 20 ± 5°C. Stephens and Malitson [54] estimated dn/dT at 20°C to be 1.36×10^{-5}/°C at $\lambda = 0.7679$ μm, increasing to 1.89×10^{-5}/°C at $\lambda = 0.4047$ μm. An uncertainty of ±5°C therefore gives an uncertainty of about ±0.0001 in n.

The values of n tabulated over the range 5 to 0.21 eV (0.25 to 5.9 μm) are based primarily on the work of Stephens and Malitson [54]. We quote their experimental values to five decimal places, and use Eq. 3 to give

values of n to four decimal places at other wavelengths. The high-energy tail of their data was extrapolated smoothly onto the n values computed from the K–K analysis of the UV reflectance. Supplemental data are included from various references [56, 58, 59]. Although we quote the NBS data [54] to five decimal places, we believe the uncertainty in the tabulated values of n in the range 0.5 to 3.5 eV is ± 0.0001. It is about ± 0.002 in the range 3.5 to 7.3 eV, and about ± 0.0005 at energies below 0.5 eV.

Irtran 5 is a hot-pressed, polycrystalline compact of MgO and has been used extensively in much infrared work. The Eastman Kodak Company no longer manufacturers it. However, the company published index-of-refraction values for this material in the range 1 to 9 μm, and a convenient list appears in the *Handbook of Optics* [60]. These data were determined experimentally and fitted to an interpolation formula by a least-squares method. Despite the different form of MgO, the values of n differ by less than ± 0.001 from the single-crystal data of Stephens and Malitson in the overlapping range (1 to 5.35 μm).

Derivations of n from reflection methods are usually less precise than those obtained via transmission. An early example is the work of Barnes *et al.* [61], who measured the reflectance of a single crystal of MgO (Norton) in the wavelength range 1 to 15.5 μm. They assumed negligible absorption in the range 1 to 8 μm and derived n in this region from the Fresnel equation for normal incidence:

$$n = \frac{(1 - \sqrt{R})}{(1 + \sqrt{R})}. \tag{6}$$

Hanna [62] found little difference between the reflectance spectra of single-crystal and polycrystalline MgO in the range 4000 to 300 cm^{-1}. Using the Fresnel equation, he derived values of n that are systematically lower than those of Stephens and Malitson by at least 0.03.

A novel approach was adopted by Welber [63], who used an index-matching technique and measured the transmission of an alkali–halide matrix containing MgO powder. This enabled him to determine n in the wavelength range 5 to 8 μm. The data near 5 μm accord well with the NBS results [54] despite the difference in the nature of the samples.

Thin Films, UV–VIS

As noted previously, the optical properties of thin films often differ significantly from those of the bulk material. In spectral regions of nominal transparency, impurities and surface defects in the film may contribute additional absorption. However, if the films contain many voids, there may be spectral regions in which values of k are less than those of bulk material.

The following section discusses thin-film data in the near-UV through near-IR regions.

Reiling and Hensley [10] prepared thin (65 nm) films of MgO by evaporating magnesium metal onto polished, cleaved LiF substrates and baking them at 650°C in air. The transmission spectra showed only a weak exciton feature superimposed on the main absorption. However, this peak moved slightly to higher energy as the temperature decreased from 25 to −170°C. Absorption coefficients, uncorrected for reflection losses, were about $2\times10^5\,\mathrm{cm}^{-1}$ near the exciton structure at 7.8 eV, and reached a maximum value of about $3\times10^5\,\mathrm{cm}^{-1}$ near 10.5 eV. The corresponding values of k are about 0.25 and 0.28, respectively, or about a quarter of the value in single-crystal material.

Malherbe [64] used an electron beam to evaporate thin films of MgO in high vacuum. He baked the films at 450°C to decrease extrinsic absorption and tried to protect them from water-vapor contamination. However, his values of n decrease from 1.99 at 0.186 μm to 1.73 at 0.248 μm, considerably lower than the single-crystal values of about 2.10 and 1.86, respectively. His k values decrease from about 0.022 at 0.198 μm to 3×10^{-4} at 0.251 μm. By contrast, Johnson's single-crystal data [33] show k values of about 1.5×10^{-5} at 0.198 μm, and Weber's single-crystal data [32] show k to be below 3×10^{-6} at 0.251 μm. Thus, the thin-film absorption in this region is two to three orders of magnitude greater than that found in single crystals.

Bradford *et al.* [65] examined the optical properties of evaporated films, using both Irtran 5 and 99.9% pure MgO as starting material. The absorption was negligible throughout the 0.22 to 8.0 μm region, and values of the refractive index derived by three different techniques (interferometric and polarimetric) agreed within 1%. The films were crystalline, with the same cubic structure and lattice constant as the bulk material, whether deposited at 50°C or 300°C onto various substrates. The crystallites were larger at the higher deposition temperature and had refractive indices identical to those of single-crystal MgO in the visible region and identical to those of Irtran 5 in the infrared. However, the refractive index of the films deposited at 50°C was about 2.3% lower, a difference attributed to the presence of more boundary-layer material between the crystallites. For the 50°C films, $n=1.70$ at $\lambda=0.55$ μm, and $n=1.62$ at $\lambda=4$ μm. The corresponding values for the 300°C films were 1.74 and 1.66.

It was noted that a hazy, bluish, scattering coating formed on films exposed to normal air [65]. Deitch *et al.* [66] used RF sputtering to prepare MgO films and observed formation of a white haze on the films after exposure to air. They measured n at only one wavelength (0.6328 μm), and found that it varied from 1.72 to 1.75 as the sputtering atmosphere was varied from part oxygen/part argon to pure argon. These values are close

to the single-crystal value of 1.7346, whereas films that were electron-beam evaporated by Kersten *et al.* [67] had n values in the range 1.684 to 1.702, depending on the substrate. These authors deposited films at 50°C as dielectric planar waveguides and derived n from knowledge of the film thickness and the angle of coupling between the waveguide and a prism for He–Ne light at 0.6328 μm. Measurements of the absorption losses indicate a value of k of about 3×10^{-5}, at least two orders of magnitude greater than that assumed for single-crystal material.

Reale [68] studied the refractive index of electron-beam evaporated MgO films as a function of the temperature of deposition onto clean, flat, soda-lime glass substrates. Impurities were removed by heating the films at 400°C in vacuum for two hours. The refractive index was determined from interference structure in the reflectance and transmittance spectra obtained with a normal-incidence, double-beam spectrophotometer. No wavelength is given, but the data are claimed to be consistent with those of Bradford *et al.* [65]. The value of n increased from 1.70 for films deposited at 50°C, to about 1.74 for films deposited at 200°C. Increasing the deposition temperature to 300°C produced a further but negligible increase in n. The films were described as being polycrystalline and the change in n ascribed to a reduction in intergranular boundaries as deposition temperatures increased.

Harrington *et al.* [69] used a laser calorimeter to measure the aborption in electron-beam evaporated MgO films. They tried to minimize extrinsic absorption by using high-purity starting material. The films were deposited onto carefully cleaned, polished CaF substrates, at temperatures in the range 50 to 200°C. Thicknesses were from $\lambda/2$ to λ at 3.8 μm, in order to simplify the subsequent optical analysis. The values of k were 2.2×10^{-3} at $\lambda = 3.8$ μm, and 6.2×10^{-3} at 2.8 μm; these values are from three to four orders of magnitude higher than found in bulk crystals.

Blanc [70] presents both n and k values for evaporated films of thicknesses 50 to 250 nm in the range 0.170 to 0.250 μm. The refractive index of these films, evaporated onto silica substrates at 250°C, is about 7% lower than that of single-crystal bulk material. However, the absortion in these films is at least two orders of magnitude greater than that of bulk material: k is about 0.001 at $\lambda = 0.2026$ μm and increases to 0.01 at $\lambda = 0.1779$ μm.

Aboelfotoh and Ramsey [71] also examined the UV absorption of electron-beam evaporated films. Their films, about 300 nm thick, were deposited onto fused-silica substrates. Spectra were recorded in the range 3 to 7 eV with a Beckmann DK-2A spectrophotometer. A variety of extrinsic absorption features were seen, which varied with deposition temperature and subsequent heating of the films in air or under vacuum. Some of this structure closely resembles that seen by other workers in MgO, which has been subjected to treatments such as X-irradiation, UV-irradiation, additive coloration, or mechanical deformation, and variously ascribed to

Fe impurities, interstitial oxygen, and so on. All the films exhibited absorption coefficients greater than $6 \times 10^4\,\mathrm{cm}^{-1}$ at 7 eV, corresponding to k values above 0.08, almost an order of magnitude greater than those in single crystals.

Maclean and Duley [72, 73] measured the transmission of MgO films prepared by the laser evaporation of high-purity Norton MgO crystals. Data were recorded in the range 0.135 to 0.240 μm for films of thicknesses between 21 and 93 nm. These films were amorphous and showed no evidence of the strong exciton structure near 0.163 μm seen in single-crystal material. The absorption coefficient did not vary strongly with film thickness but was very much larger than that of single crystals for wavelengths longer than 0.17 μm. (At shorter wavelengths, that is, to the high-energy side of the exciton feature, the films were slightly *less* absorbing than single crystals.) Annealing films in air at temperatures up to 800°C did not decrease the absorption but did produce a weak exciton structure at 0.16 μm. Other structure seen on the absorption tail of both amorphous and partially recrystallized films was attributed to absorption by surface defects, and associated with O^{2-} ions in particular.

Infrared Region

In addition to the earlier compilation of the dielectric functions [1], there are three other surveys of the infrared properties of MgO that contain optical constants: one by DeWitt of the Thermophysical Properties Research Center at Purdue [74], that by Moses from Hughes Aircraft Company [57], and the other by Whitson of the Aerospace Corporation [75]. The last contains extensive tabulations of infrared data in digital form taken from the original papers, including tables of "representative" or "best" values of n and k. This part of Whitson's work thus has much in common with the present section of this work. However, we have done a completely independent evaluation of the published infrared results, supplemented by original measurements in the regions where adequate data were missing or were questionable. Only after the infrared part of Table I was assembled was a comparison made with the Aerospace handbook values, which overall showed rather good agreement at the higher infrared frequencies.

Many measurements of optical properties have been made on MgO particulate samples, especially MgO smoke, which is easily prepared by burning magnesium ribbon in air. Extensive infrared measurements have been performed to study small-particle optical properties, such as surface modes in these samples. For an introduction to this field, Section 12.3.5 of the monograph by Bohren and Huffman [76] is suggested reading. For the purpose of arriving at the most reliable optical constants of MgO, however, we have deliberately omitted work on powders and smoke because of the complex behavior they show, and have relied exclusively on measurements

taken from bulk single crystals. Similarly, measurements on Irtran 5 have been excluded, although some comments on comparisons are included. Emphasis is exclusively on the room-temperature region.

In the infrared region the absorption of MgO begins to rise toward a reststrahlen peak in absorption near 400 cm^{-1} (25 μm). In this spectral region the absorption is so high that reflectance techniques must be employed to derive optical constants, whether by a K–K analysis of the reflectance at one angle, multiangle reflectance analysis, or by means of an oscillator fit to specular reflectance spectra. On both the low- and high-frequency sides of the restsrahlen region, there occur spectral ranges where absorption is weak enough for transmission to be carried out on cut or cleaved and polished single-crystal samples.

In this review we proceed to discuss the infrared in three regions. The first ranges from about 2000 cm^{-1} to about 750 cm^{-1} (5 to 13 μm), where multiphonon processes apparently dominate the absorption and where transmission measurements can be made. The second is the reststrahlen region, stretching from about 750 cm^{-1} down to about 300 cm^{-1}: here, k is greater than 0.1 and reflectance measurements are employed. Below 300 cm^{-1} in the far infrared, k values again fall below 0.1, low enough for transmission measurements.

Workers reporting infrared transmission measurements on solids are not always interested in extracting optical constants from their measurements, so we have had to undertake this task. When only transmission or absorptance measurements are given, it is necessary to apply a correction for surface reflection. This can be based either on measured reflectance values or on values calculated from n via the Fresnel equations. Among several possible choices for this task we have chosen the work of Piriou and Cabannes [77], who fitted reflectance data with a classical oscillator model. These authors made a special effort to achieve agreement with the accurate n values of Stephens and Malitson in the near infrared [54]. The same calculations also agree quite well with results in Duesler's thesis of K–K analysis for n tabulated from 20 to 300 cm^{-1} [78]. In addition to providing the reflection coefficients, the n values provided by Piriou and Cabannes have been used in the tabulation. It was also found that their oscillator fit [77] produced excellent agreement, both with K–K results in the far infrared at wavelengths longer than 100 μm (100 cm^{-1}) and with analysis of interference fringes in our own transmission measurements. Because of these facts, we used the same classical oscillator fit to determine the reflection corrections in the far infrared.

There have been numerous transmission measurements on single-crystal samples of MgO in the multiphonon absorption region between about 2000 and 1050 cm^{-1} (5 to 9.5 μm). The earliest work was by Barnes and coworkers [61, 79]. Burstein *et al.* [80] were concerned about some anomalies in these early data and made both reflection and transmission measure-

ments on cleaved single crystals. They present a plot of the absorption coefficient, α, rising from a value of about $1\,cm^{-1}$ near $6\,\mu m$ to over $500\,cm^{-1}$ near $14\,\mu m$. Willmott [81] measured transmission for four thicknesses of cleaved MgO ranging from 0.076 to 0.468 mm, gave tabulated values of k for 10 wavelengths, and showed a curve of both n and k from about 7 to 25 μm, parts of which were based on smoked MgO. Despite the use of a single monochromator with a natural-rock-salt prism, these measurements agree quite well with more recent work with a later generation of commercial infrared monochromators. Other such measurements are reported in the papers by Oppenheim and Goldman [82], Billard *et al.* [83], Cabannes and Billard [84], and Hanna [62].

The values of k tabulated in the range 6 to 14 μm rely primarily on two papers, one by Gourley and Runciman [85] and the other by Piriou and Cabannes [86]. Gourley and Runciman measured the transmission of 0.037 to 5 mm-thick cleaved and ground platelets and presented their data in the form of absorption coefficient spectra at 35 and 305 K. Piriou and Cabannes [86] cleaved and polished samples to thicknesses ranging from 0.064 to 20 mm, and reported measurements at 77 and 273 K. They present transmission curves as far as $1700\,cm^{-1}$ and the corresponding absorption coefficient data over the spectral range 700 to $1500\,cm^{-1}$ (14.3 to 6.7 μm).

In the region from 2000 to about $1000\,cm^{-1}$, there are systematic differences between the two sets of data [85, 86]. The Piriou and Cabannes values become increasingly lower than those of Gourley and Runciman toward higher frequencies, but in agreement with Ref. [83]. The difference approaches a factor of two at $1700\,cm^{-1}$. We made an attempt to resolve this discrepancy by making our own measurements on cleaved MgO, with results intermediate between the two. The absorption in this spectral region is dominated by contributions from nonintrinsic proceses, and we believe that the differences in the data reflect differences between individual samples and between sample-preparation techniques. The values of k selected for Table I in the range 1700 to $1050\,cm^{-1}$ are based on the Piriou and Cabannes data [86], because of their lower values.

From 1050 to $750\,cm^{-1}$ there is excellent agreement between values of k derived from the absorption coefficients of Piriou and Cabannes and from the optical density curves (absorptance) of Gourley and Runciman [85]. Values in the table are taken from the smoothed curve of these data plots and therefore represent the average of these two sources.

The absorption rapidly rises in the region below $800\,cm^{-1}$, and it becomes impractical to produce samples from bulk single crystals that are sufficiently thin to make transmission techniques useful. Although some of the older works resorted to smoke or powder samples, it seems preferable to use reflectance techniques on single-crystal material, if one is interested in the intrinsic optical properties. One of the earliest analyses by reflectance techniques was by Häfele [87], who used reflectance at two different

angles to derive optical constants. Jasperse *et al.* [88] measured near-normal-incidence (11°) reflectance on single-crystal samples that had been cut, polished, and annealed. Measurements were made from 200 to 800 cm^{-1} at several temperatures in the range 8.5 to 1950 K. The data were analyzed by fitting the reflectance with a two-oscillator classical dispersion model, using the equations

$$\varepsilon_1 = n^2 - k^2 = \varepsilon_\infty + \sum_j \frac{4\pi\rho_j \nu_j^2(\nu_j^2 - \nu^2)}{(\nu_j^2 - \nu^2)^2 + (\gamma_j \nu)^2} \tag{7}$$

$$\varepsilon_2 = 2nk = \sum_j \frac{4\pi\rho_j \nu_j^2(\gamma_j \nu)}{(\nu_j^2 - \nu^2)^2 + (\gamma_j \nu)^2}. \tag{8}$$

Kachare *et al.* [89] reanalyzed these results and emphasized the superiority of using a K–K analysis of the reflectance data. Piriou and Cabannes [77] made similar specular-reflectance measurements between about 300 and 1000 cm^{-1} and analyzed the measurements with both a two-oscillator fit and a K–K analysis. These authors had previously made extensive studies of absorption in MgO outside of the reststrahlen region [86] and used the results in adjusting the oscillator parameters for proper fits to these accurate k values. It was for this reason that we adopted their model to calculate reflection corrections at both lower and higher frequencies than the reststrahlen region, as mentioned earlier. The oscillator parameters used by Piriou and Cabannes are

$$\varepsilon_\infty = 2.964,\ \nu_1 = 396\ cm^{-1},\ 4\pi\rho_1 = 6.80,\ \gamma_1/\nu_1 = 0.0192,$$

$$\nu_2 = 643\ cm^{-1},\ 4\pi\rho = 0.043,\ \text{and}\ \gamma_2/\nu_2 = 0.140.$$

Andermann and Duesler [90] paid considerable attention to factors affecting the K–K results for MgO, especially in the very low reflectance region near 840 cm^{-1} and in the shoulder region at about 720 cm^{-1}, where the reflectance is rapidly rising. These authors showed that even the position of the maximum absorption peak near 400 cm^{-1} can be affected by slight errors in these regions away from the peak. By taking special care in these regions they have analyzed a composite of their own reflectance data and those of Piriou and Cabannes [77] to obtain a revised set of optical constants derived from the K–K technique. The values are available in tabular form in the thesis of Duesler [78] and are those presented in Table I

for the range 740 to 320 cm^{-1}. There is, in fact, very little difference (averaging a few percent relative difference) in the range 740 to 400 cm^{-1} between the various k values taken from the oscillator fits of Piriou and Cabannes [77] and Jasperse *et al.* [88], and the K–K technique of Andermann and Duesler [90]. In the 400 to 300 cm^{-1} region, where k rapidly decreases, there are much greater differences (approaching a factor of two).

In the far infrared beyond the strong reststrahlen peak, there are some distinct gaps in the reported optical constants of single-crystal MgO. This situation is worse for the 100 to 300 cm^{-1} region than below 100 cm^{-1}. In the latter region, Rowntree [91] determined k values from measurements of transmission. Billard *et al.* [92] measured absorption in monocrystalline samples of several thicknesses in the 20 to 350 cm^{-1} spectral range, and at temperatures of 300 to 1350 K. Unfortunately, they plot absorption coefficient versus temperature at only three frequencies: 50, 70, and 90 cm^{-1}. At higher frequencies up to about 300 cm^{-1}, where we feel the K–K results become suitably accurate, we could find no pertinent measurements except for those of Hanna [62], used in Whitson's compilation [75]. However, these data were for hot-pressed powders of MgO, and not necessarily characteristic of bulk-single-crystal values.

Because of the inadequate information about the absorption in the spectral region between 100 and 300 cm^{-1}, one of us (DRH) collaborated with W. Kratschmer to fill this gap. A Fourier-transform infrared spectrophotometer was used to make transmission measurements at room temperature on cleaved slabs of MgO. The thicknesses were 0.0405, 2.55, and 6.12 mm. Further details of these measurements and a discussion of their physical implications will be published elsewhere [93], but we believe the k values themselves are useful enough to include in the present compilation. Our own recent measurements agree rather well with those of Rowntree [91] within the region of overlap up to 85 cm^{-1}, so we have used his values at lower wave numbers in Table I. Rowntree estimates the experimental uncertainty in his room-temperature measurements to be $\pm 20\%$. This may be on the conservative side; our independent determinations of k in the 50 to 85 cm^{-1} region agree with his to better than 10%. Above 85 cm^{-1}, however, measurements on our 0.0405 mm sample depart seriously from the high-frequency tail of the Rowntree curve. Our data rise to a peak at about 105 cm^{-1}, followed by a gentle decline toward higher frequencies. Billard *et al.* [92] qualitatively described a somewhat similar behavior as "absorption abruptly rises to a considerable level at 100 cm^{-1} and then stays at this level over about 100 cm^{-1} before increasing again." These authors did not give the spectral absorption curve. Our values for k quoted in Table I are probably accurate to within about 10% except toward the high-frequency end, where increasingly small transmission may limit the accuracy to about 30% at the last point. There remains the region 275 to

300 cm^{-1}, where there appears to be no good data, but a reasonable extrapolation now appears to be possible in this gap.

As noted earlier, the values of n in Table I in the region below 270 cm^{-1} are based on a classical oscillator fit to reflectance data [77]. However, Rowntree [91] made a more direct experimental determination of n from interference spectra in the range 100 to 10 cm^{-1}. His values agree to within about ± 0.01 with those in Table I.

For completeness, we note that the commonly accepted value of the static dielectric constant, ε_0, is 9.8. This was obtained experimentally by a capacitance technique by Højendahl [94] and later by analysis of optical data [91, 95].

ACKNOWLEDGMENTS

We thank Drs. N. C. Fernelius (Wright–Patterson Air Force Base, Dayton), J. L. Freehouf (IBM, Yorktown Heights), W. F. Hanson (University of Texas, Radiological Physics Center), D. R. McKenzie (University of Sydney, Australia), and E. T. Arakawa and Y. Chen (both of Oak Ridge National Laboratory, Tennessee), for providing us with further information, including digitized data, from their original research.

In the papers to be discussed, a variety of polyethylenes have been studied, so one cannot hope to collect n and k over a wide spectral range for a given type of material. Luckily, the variations among materials are usually less than a factor of two where spectra overlap.

Ideal polyethylene forms a planar (zigzag) carbon chain constructed with C═C and C═H σ bonds only (see inset in Fig. 1). The unit cell contains two C_2H_4 molecules. Normal commercial low-density polyethylene is usually around 80% crystalline [1]. Partridge [2], however, reports a crystallinity of only 55%. The values of bond length and bond angle are 1.53 Å and 112°, respectively. The refractive index for amorphous specimens is given as 1.49 and for crystalline material as $\alpha \approx \beta = 1.52$ and $\gamma = 1.582$ at $\lambda = 5461$ Å (where α, β, and γ are the refractive indices along the a, b, and c crystallographic directions) [3–5].

Light-scattering experiments made by Partridge [6] have shown considerable scattering by thick polyethylene samples. A method of correcting for light scattering has been discussed in this paper.

Optical properties of polyethylene in the photon energy range 76–0.5 eV have been measured by Painter *et al.* [7]. Various transmission techniques were used over nearly the entire range; free-standing Glad Wrap (Union Carbide registered trade name); Dow Corning polyethylene pellets evaporated onto one half of a MgF_2 disk; polyethylene evaporated onto one half of a thick layer of *p*-terphenyl covering a glass slide. The *p*-terphenyl is fluorescent, so light passing through the polyethylene produces light emission in the *p*-terphenyl, which is measured through the glass slide. It is probable that the polyethylene was not highly crystalline (and perhaps it was even amorphous). The UV structure is primarily due to the chain carbon atoms and is probably similar for crystalline or amorphous polyethylene. We assume unpolarized light was used and that normal incidence

was maintained with the Cary and Seya–Namioka monochromators used. The index of refraction was measured using a critical-angle measurement. A polyethylene film was deposited onto the flat side of sapphire hemicylinder. The angle of incidence was varied to detect the critical angle. Painter *et al.* extrapolated their k values to high energy and calculated the contribution of the C atomic scattering cross-section at 282 eV. Although there is concern about light scattering in polyethylene (samples are often not clear to the eye), this does not appear to have been a problem into the short-wavelength UV. The results for n and k obtained from tables and graphs in Ref. [7] are listed in Table I and plotted in Fig. 1.

Ritsko [1] reported measurements on films of polyethylene prepared from solvent evaporation. The thickness of the films was about 1000–2000 Å. They obtained values of the real and imaginary parts of the dielectric constants from measurements of energy-loss spectra and application of Kramers–Kronig analysis. The energy-loss spectra of an electron beam were recorded as a function of scattering angles θ or momentum transfer Φ. The samples were exposed to the incident beam for five minutes at $\theta = 0$. The energy-loss probability or differential scattering cross-section per unit energy loss E per unit solid angle Ω is a function of ε, the complex dielectric response function with real and imaginary parts ε_1 and ε_2, respectively [8].

Since the energy-loss spectrum is proportional to the energy-loss function $\mathrm{Im}(-1/\varepsilon)$, the constant of proportionality can be determined by normalizing the spectrum to the known value of the refractive index 1.4907 at 2.22 eV [9]. In addition, a correction for multiple inelastic scattering was made for the spectrum. Once the energy-loss function was normalized and multiple scattering eliminated, the function $\mathrm{Re}(-1/\varepsilon)$ was computed from the Kramers–Kronig relation, and hence, ε_1 and ε_2 could be calculated [10]. The complex refractive index $(n+ik) = \sqrt{\varepsilon}$ is listed in Table I. Where overlap occurs, these values agree well with those of Painter *et al.*

The n curve shows a peak near 7.2 eV. The peak was also reported by Tanaka [11]. This peak in n gives an approximate value for the optical band gap.

The values of the absorption edge show considerable variation as reported by different authors [12]. This is likely to have been caused by the choice of polyethylenes used (high density or low density) and the difference in the preparation of specimens. The drawn-film samples exhibit anisotropy.

The values of refractive index obtained for polyethylene depend critically on the method of film preparation. The density of the film depends on the method of preparation. It is possible to introduce methyl groups (CH_3) and vinyl groups (C_2H_3) into the regular $=CH_2=CH_2=CH_2=$ sequence. If the number of CH_3 groups per 1000 C atoms is 83, the refractive index

for the Na D line (5890 Å) is 1.5060; it increases to 1.5260 when 16 CH_3 groups are present per 1000 C atoms (see inset in Fig. 1).

The variation of refractive index with temperature for low-density polyethylene seems to be greater than that for high-density polyethylene. The variation for a temperature change from 70° to 124 °C is about 0.05 for low-density polyethylene, and from 130° to 154 °C it is about 0.07 for high-density polyethylene.

The properties of polyethylene films prepared by the solvent-evaporation technique are dependent on a number of parameters, such as the solvent used, the starting concentration, the temperatures, and speed in cases when the evaporation was effected by centrifugal rotation.

At a spin speed of 3000 RPM, a solution of 0.05% by weight of polyethylene in CCl_4 yields films of density 0.914 gm/cm^3 and refractive index $1.459 + i0.023$ at 2.254 eV; when the concentration is increased to 0.4% by weight, the refractive index changes to about 1.502. When the spin speed increases to 4000 RPM, the 0.4% concentration solution gives films of refractive index 1.457 [13].

A change in solvent also makes a difference. A starting solution of low-density polyethylene in xylene with 0.05% by weight at a spin speed of 1000 RPM yields films of density 0.923 gm/cm^3 and refractive index $1.464 + i0.021$ at 2.254 eV. When the concentration is increased to 0.4% by weight, the refractive index changes to $1.501 + i0.004$. When the specimen speed increases to 4000 RPM, the 0.4% by weight solution yields films of refractive index $1.495 + i0.011$ [13].

Although the vibrational absorption bands of polyethylene are well-known, we could not find a determination of the optical constants in the 2–20 μm region. The structure of crystalline polyethylene was determined long ago, and most spectroscopic efforts were directed towards assigning the many vibration modes of the various kinds of polyethylene (14–17). These include the orthorhombic crystal with two CH_2 groups repeating themselves in zigzag carbon skeleton chains throughout the crystal: $(C_2H_4)n$. However, various types of branching can occur, which lead to subtle additional features in the spectrum, and methyl and vinyl groups can occur along the chains. Although Krimm *et al.* [14] measured spectra of oriented crystal samples with polarized light, we have elected to use unpolarized spectra of Nielsen and Woollett [15] to determine approximate k values. They present transmittance spectra of a specific kind of polyethylene (Marlex 50) for three thicknesses. Marlex 50 is 95% crystalline with less than two methyl groups per 1000 carbon atoms and one vinyl group per molecule (for each C_2H_4 molecule, one H is missing). Nearly all the absorption lines (designated s (strong), m (medium) and w (weak)) are the same in a number of different polyethylenes [17].

We assumed $n = 1.5$ throughout the near IR and calculated k using the equation $T/T_o = (1 - R)^2 \exp(-\alpha x)$, where R is the single-surface reflecti-

vity $R=(n-1)^2/(n+1)^2$, since $k \ll n$ in the near IR; $\alpha=4\pi k/\lambda$ is the absorption coefficient, and x is the film thickness. This formula assumes that interference effects are averaged out, which is suggested by most of the spectra. Because k is small even at vibrational resonances, the dispersion should be small, and assuming that n is a constant is reasonable. The k values outside of resonances varied by as much as a factor of two among the three thicknesses, suggesting some scattering effects especially at shorter wavelengths. We suggest that the k values at resonances are probably good to $\pm 30\%$. In Fig. 1 the density of absorption lines is so great that it is not possible to resolve every line, although in Table I every line is defined by several data points. We have rounded off the k values to two significant figures; this loses only a few weak structures in the spectrum.

In the far-infrared region of the electromagnetic spectrum ($\lambda > 20$ μm), polyethylene is one of the most widely used materials for the fabrication of optical elements such as windows and lenses. This is due not only to its transparency, but also to its availability, low cost, machinability, and relative stability. As a consequence, its power transmission properties in this spectral region have been studied by many authors (see, for example, some reviews [18–20]). However, the optical properties of polyethylene, and indeed of many other polymers in the far infrared, are known to be specimen dependent, and can vary significantly depending on the past history of the specimen. In this spectral region, for example, it is not unusual to find differences of up to a factor of two between the absorption spectra of specimens with different histories. Some of the factors that affect this will include the particular manufacturing process used (extrusion, or vacuum- or injection-molding) and the density and degree of crystallinity achieved in the final material. The optical properties will also be varied by the presence in the material of impurities such as antioxidants, agents to improve flow during the manufacturing process, heavy-metal salts or oxides as residues of the catalysts used in polymerization, and microdroplets of water. Similarly, exposure of the material to environmental factors such as high temperatures, ultraviolet radiation, mechanical stress, and high-energy irradiation can significantly change the far-infrared optical constants of this material. It is therefore difficult to arrive at a unique set of intrinsic optical constants for polyethylene in the far-infrared. This problem is further aggravated by the fact that although there have been many measurements of the transmission properties of this material, there is little detailed quantitative information available on the spectral variation of both optical constants over this region. This critique will discuss, therefore, such data as are available with a view to providing typical values of the optical constants and their spectral variation across the far infrared. These values can be used to give reasonable calculations of the consequences of using a polyethylene-based optical element in an optical system. However, in applications where such calculations are critical to an evaluation of

system performance, it might well be best to measure the optical constants of the particular piece of polyethylene that is to be used. In most of the original publications the measurements have been made by Fourier-transform spectroscopy, so the independent spectral variable is given as wave number in reciprocal centimeters. Similarly, in most far-infrared measurements the dissipative part of the complex refractive index is usually described by the power absorption coefficient, α, rather than the extinction coefficient, k. The two parameters are related by

$$\alpha = 4\pi\nu k, \tag{1}$$

in which ν is the wave number.

The best optical-constant data for polyethylene in the far infrared are presently provided by the technique of dispersive Fourier-transform spectroscopy (DFTS) [21–23]. This is because of the measurement precision and accuracy that can be achieved, together with the wide broad-band spectral coverage available with the technique. Under the ideal conditions of a perfectly homogeneous, plane-parallel-sided specimen, measurements that are limited by random uncertainties of better than parts in 10^5 in the refractive index and better than a few percent in the extinction coefficient can readily be achieved for a low-loss material such as polyethylene. Ideal conditions, however, are rarely found for a mechanically soft material such as polyethylene. Nonetheless, some of the DFTS measurements on this material will be seen to provide the most representative optical-constant data set. In this technique both the attenuation and the phase shift imposed on an electromagnetic wave that propagates through a specimen are directly measured, and the optical constants calculated from these measured parameters via Fresnel's relations for the complex transmission and reflection coefficients of an interface between dissimilar media.

Most of the DFTS studies on polyethylene have been at near-millimeter wavelengths. The first of these [24, 25] covered the spectral region between 4 and 40 cm^{-1} (wavelengths from 2.5 mm to 250 μm) and reported the results of measurements at a temperature of 290 K on specimens of low- and high-density polyethylene, although density values were not given. These optical-constant spectra reveal the general behavior found in such measurements on polyethylene. The refractive index spectra (refraction spectra) are virtually wave number independent at the parts-in-10^3 level, taking mean values of 1.5138 for low-density polyethylene (LDPE) and 1.5246 for high-density polyethylene (HDPE). The power absorption coefficient spectra for the two densities both increase monotonically with increasing wave number, with that of LDPE being systematically some 0.002–0.006 cm^{-1} below that of HDPE. Typically, the random uncertainties in these measurements were estimated to be between ±0.002 and

$\pm 0.005\,\mathrm{cm}^{-1}$ in the absorption coefficient, corresponding to random uncertainties of a few times 10^{-5} in the extinction coefficient. In the refraction spectra the random variation was about 10^{-5}, increasing to a few times that at either end of the measured spectral range.

Other subsequent near-millimeter-wavelength DFTS measurements on HDPE [26, 27] at a temperature of 299 K with, again, an unspecified density, gave absorption spectra in broad agreement with the earlier studies, although the mean level of the refraction spectrum (~1.5184) fell between those of the earlier LDPE and HDPE measurements. DFTS measurements of the temperature variation of the refraction spectra of the same LDPE and HDPE specimens measured in the 290 K measurements of Birch *et al.* [24, 25] have been made between 4.2 and 300 K in the spectral region 10 to $30\,\mathrm{cm}^{-1}$ [28]. These showed the overall level of the refraction spectrum to increase with decreasing temperature between 300 and 40 K, as one would qualitatively expect on thermal-contraction grounds, and then to decrease slightly down to 4.2 K. At temperatures near 300 K the slope of both refraction temperature data sets varied at a rate of approximately $-2.5 \times 10^{-4}\,\mathrm{K}^{-1}$. In both LDPE and HDPE these measurements showed the overall level of the refraction spectra to increase by about 2.5% and 2.8%, respectively, between 300 and 40 K.

Moving away from the near millimeter into the far infrared, one finds DFTS measurements on polyethylene at a temperature of 298 K in the spectral range from ~30 to $200\,\mathrm{cm}^{-1}$ [29, 30]. Although the overall level of the refraction spectra in these works is consistent with that of the near-millimeter-wave studies, both the refraction spectrum and the corresponding absorption spectrum appear with quite large discrete features. One of these, the $73\,\mathrm{cm}^{-1}$ B_{1u} lattice mode [31, 32] is a well-known feature of the infrared spectrum of polyethylene, but the other features near 105 and $142\,\mathrm{cm}^{-1}$ are reported for the first time. It may be best to treat these as either measurement artifacts of some kind or as representing some extrinsic contribution to the optical constants from some unexpected impurity. There are two reasons for this, in addition to that of these measurements being the only observation of such structure in polyethylene spectra. First, in one case [29], the absorption spectrum is shown accompanied by that for a specimen of the polymer TPX, another widely studied far-infrared material. This also contains discrete features at similar wave numbers. One at $105\,\mathrm{cm}^{-1}$ has not been reported in other studies on TPX; one at $141.7\,\mathrm{cm}^{-1}$ has been seen in other measurements [33, 34], but only as a weak, rather narrow band, and not as prominent and as broad as shown in Afsar *et al.* [29]. The second reason for discounting these features as intrinsic features of the polyethylene spectrum cómes from the lack of consistent corresponding dispersion in the refraction spectra. The two features in the absorption spectrum are very similar in width and intensity, and one would therefore expect to observe similar dispersions in the

refraction spectrum, whereas one finds a region of dispersion across the 142 cm^{-1} position but none in the region of 105 cm^{-1}.

There have also been other, more recent, DFTS measurements on polyethylene in the far infrared [35] that do not show the discrete features found in Afsar *et al.* [29, 30]. These were on both LDPE and HDPE in the spectral region from 50 to 450 cm^{-1} at a temperature of 293 K. The densities of the two specimens were not given. The corresponding spectra for the two specimens are qualitatively similar in their larger-scale features. The random uncertainties in these spectra were estimated as about 10^{-5} in the refraction spectra and about 0.05 cm^{-1} in the absorption spectra, over most of the measured spectral range. Both absorption spectra clearly show the B_{1u} lattice mode in the region of 73 cm^{-1}, although it is nearly three times more intense in the HDPE spectrum, reflecting the higher degree of crystallinity in that specimen. The two refraction spectra similarly show the corresponding dispersion associated with the band. At higher wave numbers the HDPE absorption spectrum increases with increasing wave number to reach a broad maximum in the region of 200 cm^{-1}, before falling to a shallow minimum around 300 cm^{-1}, and then rising again. The HDPE refraction spectra falls to a shallow minimum between 200 and 250 cm^{-1}, and then rises with increasing wave number to be consistent with the increasing absorption. The LDPE spectra show similar overall behavior, although the broad band is present only as a shoulder in the absorption spectrum. Both refraction spectra show a clear but small localized region of dispersion in the region of 94 cm^{-1} with corresponding weak shoulders in the absorption spectra. Fleming *et al.* [36], in a study of temperature effects in the far-infrared absorption of polyethylene, assign a weak band at 94 cm^{-1} to the B_{2u} lattice band, which was first observed at 110 cm^{-1} at a temperature of 2 K [37].

There have been a considerable number of measurements of the power transmission spectrum of polyethylene in the far infrared using conventional Fourier-transform spectroscopy (FTS). Such measurements can be converted into optical-constant data in a number of ways. First, if the measurements are such that a channel spectrum due to multiple-beam interference between internally reflected rays is resolved, then various methods exist for deriving a refractive-index spectrum from the period of the channel spectrum. The measurements can then be repeated or the results reprocessed to give a spectrum with reduced spectral resolution and no channel spectrum. The refraction spectrum can then be used to derive the absorption spectrum from the transmission spectrum. If channel-spectra methods are not used, then a value for the refractive index could be taken from the literature, for example, and used to calculate the absorption spectrum from the transmission spectrum. Alternatively, measurements can be made on two specimens of different thicknesses of the material under investigation. The absorption spectrum is then calculated

from the ratio of the transmission spectra of the two specimens using an expression that assumes single-pass transmission through the specimens, with no contributions from internally reflected rays. In many of the FTS measurements on polyethylene the manner in which the absorption spectrum has been obtained is often not explicitly stated. It can be difficult, therefore, to assess such data, especially if they differ in a significant way from other results.

Loewenstein and Smith [38] developed a channel-spectrum method and published a number of papers on the far-infrared optical constants of a range of materials, including high-density polyethylene [39]. Over their measured wave number range of 50 to 250 cm^{-1} the derived refraction spectrum was virtually constant at a level of about 1.520 with an experimental uncertainty of 0.1% (~0.001), which is consistent with the DFTS results of Birch [35] on HDPE, given the absence of quoted density values. The measured absorption spectrum of the specimen of Smith and Loewenstein [39], however, is up to a factor of two greater than those of both the DFTS studies already discussed and of non-DFTS studies to be discussed subsequently. Their spectrum is presented with estimated uncertainties, presumably random, of about 10%. Again, given the uncertainties imposed by the lack of knowledge of specimen history, it is not possible to discuss such differences in the context of specimen-to-specimen variations or systematic measurement errors. However, the absorption measurements of Smith and Loewenstein [39] are certainly unusual in that they show no B_{1u} lattice mode in the vicinity of 73 cm^{-1}. Coleman *et al.* [40] have also used a channel spectrum approach to determine the optical constants of both LDPE and HDPE between 25 and 500 cm^{-1}. Although their absorption spectra are not dissimilar from those of the other measurements considered in this critique, their refraction spectra show overall dispersions across this spectral range (~0.03 for LDPE and ~0.08 for HDPE) that are more than an order of magnitude greater than those found by the various DFTS studies.

Measurements by Chantry *et al.* [41] are representative of what can be achieved by two-thickness FTS methods. They derived the absorption spectrum of both LDPE and HDPE in the region from 20 to 220 cm^{-1}. In addition to the broad-band FTS measurements, the coefficient at 29.7 cm^{-1} was also derived from transmission measurements made using a hydrogen-cyanide laser as a radiation source. The measurement temperature was not specified, but was clearly that of the ambient laboratory environment from the description of their apparatus. Specimen densities were not given. In the spectral region above 50 cm^{-1} their absorption spectra are in general agreement with other FTS and DFTS studies, with a clearly resolved B_{1u} band at 73 cm^{-1} superimposed on the increasing background absorption to higher wave numbers. In the region below 50 cm^{-1} Chantry *et al.* found little difference between the absorption spectra of LDPE and HDPE,

which is consistent with the DFTS data of Birch *et al.* [24, 25], which found differences of less than 0.006 cm^{-1} between the spectra of the two forms of the material in the region below 40 cm^{-1}. Chantry *et al.* were able to fit their absorption data to the following quadratic:

$$\alpha(\nu) = 8 \times 10^{-4}\nu + 1.4 \times 10^{-4}\nu^2 \tag{2}$$

in the wave number region between 2 and 50 cm^{-1}. Their HCN-laser determination of the absorption coefficient at 29.7 cm^{-1} was in good agreement with the value predicted by Eq. 2.

The spectrum calculated from Eq. 2 gives a reasonable fit to most of the published data on polyethylene in this spectral region, although it predicts values that are somewhat below the trend of some of the DFTS near-millimeter-wave measurements. It would not be unreasonable, therefore, to use it to provide a guide to expected absorption levels, although as discussed previously, for some applications it might be prudent to determine the absorption spectrum of the particular material to be used. Chantry *et al.* [41] proceeded to derive an equation for the spectral variation of the loss tangent of polyethylene from Eq. 2. One should note two things about this: first, that it was stated to have been derived using a value for the refractive index (1.461) that is lower than those generally associated with either LDPE or HDPE, and which may have been taken from earlier hydrogen-cyanide laser measurements at 891 GHz [42]); second, that the numerical constants of that equation are not consistent with that value of the refractive index. The correct values would be slightly different.

There have been a number of monochromatic determinations of the optical constants of polyethylene using coherent sources. Bicanic and Dymanus [43], for example, have determined the absorption coefficient at 29.7 cm^{-1} of a unspecified specimen 0.21 mm thick, at room temperature using an HCN laser to measure its power-transmission coefficient. They used a literature value of the refractive index to correct for reflection effects and found a value of 0.27 cm^{-1}, which is about twice the values given by DFTS studies and predicted by Eq. 2. If one were to assume the Eq. 2 value, the absorption loss for this specimen would be about 3% in the presence of a 7% reflection loss. Such a small loss could easily be obscured by systematic effects in a measurement with coherent radiation. This could well account for their relatively high value.

Llewellyn-Jones *et al.* [44] have determined the absorption coefficients of LDPE and HDPE specimens with densities of 0.89 and 0.93 $g\,cm^{-3}$, respectively, using an untuned cavity technique at 156 GHz (5.2 cm^{-1}). Their results of 0.013 and 0.012 cm^{-1}) (LDPE and HDPE) are somewhat higher than the prediction of Eq. 2 (0.008 cm^{-1}), but in good agreement

with DFTS results [24–27].

Monochromatic measurements can also be used to determine the refractive index. Early measurements by Chamberlain and Gebbie [42], for example, demonstrated how a Michelson interferometer and a laser source could be used to give such information, by placing the specimen within one arm of the interferometer and rotating it slightly to vary the optical path through the specimen. Such a measurement on polyethylene led to a value of 1.461 ± 0.023 at 337 μm wavelength, which is low in comparison with more recent values.

Stützel *et al.* [45], in a noninterferometric approach, used the Abbe method in which the refractive index is found from the angle of incidence that causes a right triangular prism to retro-reflect incident radiation. With this method Stützel *et al.* determined the refractive indices of polyethylene specimens of different, quoted, crystallinities at 296 K for wavelengths of 118 and 570 μm using an optically pumped gas laser. In addition, they determined the temperature variation of the refractive index of a 27% crystalline specimen between 5 and 290 K at an unspecified wavelength, but presumably either 118 or 570 μm. Their result showed the refractive index generally increasing with decreasing temperature in good agreement with previous DFTS results [28], although their finer temperature resolution revealed abrupt changes of slope at 50 and 110 K, whereas only the former had been seen in the DFTS study. Near to room temperature, Stützel *et al.* found the slope of their data to be approximately $-13 \times 10^{-4}\,K^{-1}$, which is larger than the $-2.5 \times 10^{-4}\,K^{-1}$ of the DFTS measurements [28], but this difference may again only reflect the finer temperature resolution of the former study. Alvarez *et al.* [46] have also measured the refraction spectrum of a Rigidex polyethylene between 50 and 200 cm^{-1} at 1.6 and 300 K. They found a 6% increase in the overall level of the refraction spectrum in going to 1.6 K, which is about twice that found in the other temperature-variation studies [28, 45].

In this next section the results of a number of papers are discussed to illustrate the extent to which the optical constants of polyethylene will depend on extrinsic factors, which prevent one from talking in terms of unique intrinsic data for this material. Davies and Haigh [47] and Ayers *et al.* [48], for example, describe the results of FTS absorption studies on both LDPE and HDPE specimens manufactured by a vacuum-melt extraction and casting technique, which produces bulk material from polymer powder free of additives. The processing avoids oxidation effects and removes volatile impurities and microscopic gas bubbles. Materials produced by this process were shown to have absorption spectra reduced by factors of up to two from those generally associated with this material in the far infrared. In addition, microwave bridge measurements [48] showed loss-angle reductions by a factor of three at 27.8 GHz. To the extent that this vacuum-melt extraction process yields purer material than that generally available

for far-infrared applications, these measurements of its absorption spectra [47, 48] may be taken as providing a close approach to the intrinsic-polyethylene absorption spectra.

There have been a number of studies of the variation in line position of the B_{1u} and B_{2u} lattice modes with various macroscopic parameters. Bank and Krimm [32], for example, used a grating spectrophotometer to make transmission measurements at temperatures of 103 and 303 K, which demonstrated the sensitivity of the line shape, line intensity, and line position of the B_{1u} mode to both temperature and degree of crystallinity. Similar FTS-based measurements have been reported by Zirke and Meissner [49]. These are the effects that cause significant changes to the optical constants only in the region within about 5 cm^{-1} of line center, and will not be relevant to many applications. Nonetheless, it is important to be aware of them. Other similar temperature-dependent studies have been reported by Fleming *et al.* [36], Stone and Williams [50], Frank *et al.* [51], and Goldstein *et al.* [52]. Frank *et al.* [53] report the appearance of an absorption band at 39 cm^{-1} in the absorption spectrum of high-pressure annealed specimens when the specimen temperature was below 170 K. The band intensified with decreasing temperature but did not shift its position.

There have also been some far-infrared studies of the effects of neutron and gamma-ray irradiation on the optical constants of polyethylene. Frank [54], for example, has demonstrated the effect that high-energy irradiation has on the absorption spectra of LDPE and HDPE in the region between 50 and 90 cm^{-1}. The intensity of the B_{1u} mode was not affected, whereas the overall level of the broad background absorption was almost doubled for radiation doses of 50 Mrad. Eberhagen and Fahrbach [55], working at much higher radiation doses, demonstrated an onset of radiation-induced transmission loss at doses above 10^9 rad, which led to a fourfold reduction in the transmission coefficient of a specimen 5 mm thick at 0.2 mm wavelength (50 cm^{-1}) by a dose of 10^{10} rad.

Finally, it is well-known that the application of stress to a polymer, either during its manufacture or subsequently, will yield material in which the molecular chain axes are preferentially aligned in certain directions. This will result in the optical constants exhibiting both birefringence and dichroism. Jacobsson and Hård [56], for example, using what was essentially a monochromatic version of DFTS, found birefringence, which varied with spatial position by between 0.01 and 0.025 at a wavelength of 70.5 μm in an injection-molded specimen of HDPE. Similarly, Read *et al.* [57] report the results of birefringence measurements on a LDPE sheet 0.33 mm thick, which had been stretched to a draw ratio of one to four; it was found to have a virtually constant in-plane birefringence of 0.016 from 0.546 μm wavelength in the visible, though the far infrared, and out to 8.6 mm wavelength in the microwave.

In conclusion, then, concerning the optical constants of polyethylene in

the far-infrared spectral region, one can see the difficulties of arriving at a definitive set of data that represents the intrinsic properties of this material. It is much easier instead to define a reasonably representative set of spectra for the real and imaginary parts of the complex refractive index, which one can use as a guide to expected, typical values. Thus, some of the DFTS results that have been discussed [24, 25, 35] have been used to supply such data, and these are presented in Fig. 1 and Table II. These references were chosen in part because they offer the widest spectral coverage combined with precise and accurate data, data with sufficiently low random uncertainties that the weak refractive-index dispersion associated with the intrinsic lattice modes is clearly resolved. They were chosen also because they were readily available to the author in a tabulated form and did not need to be read from a graph with the consequential loss of accuracy. This should not be taken as a claim for any special status for this data. Given the problem of specimen-to-specimen variation that this critique has discussed, these data should be taken only as typical of what might be found in a particular specimen. The far-infrared spectrum of Fig. 1 is not a definitive polyethylene spectrum. In Fig. 1 the featureless line labeled n represents the refractive index of both LDPE and HDPE material. The small differences between these spectra, and their dispersions, cannot be seen on the scale of the figure. The two curves labeled LDPE and HDPE represent the far-infrared k spectra [35]. The curve labeled a is a composite from the near-millimeter-wave k spectra of both LDPE and HDPE of Birch *et al.* [24, 25]; the curve labelled b is the k spectrum calculated from Eq. 2. Since the details of the refraction spectra are not resolved in Fig. 1, they are shown replotted on expanded scales in the linear–linear representation of Fig. 2. Now the dispersion due to the 73 cm^{-1} mode is seen clearly.

[a] References are given in square brackets.
[b] n = 1.5 was assumed constant down to 670 cm^{-1} for the calculation of k.

Potassium Bromide (KBr)

EDWARD D. PALIK
Institute for Physical Science and Technology
University of Maryland
College Park, Maryland

The selected optical constants n and k are collected in Table I and plotted in Fig. 1. There is some overlap of data to indicate the typical variations that occur from lab to lab. The eV, cm^{-1}, or μm units of the original data are usually listed with three or fewer significant figures (eV, for example, as read off a graph), and the other two units (cm^{-1} and μm) are listed with four figures. Although n and k are often listed with two decimal places (and at least three significant figures) in the IR and UV, the accuracy (absolute value) is probably poorer, but the precision is good enough to show structure in the original measurements (multiphonon peaks in the IR and peaks in interband absorption in the UV). In the transparent visible and near-IR regions, n is known to four or five figures.

Starting at low frequency, we note that a simple capacity measurement of the loss tangent, $\tan\delta = \varepsilon_2/\varepsilon_1$, and the real part of the dielectric function, ε_1, have been nearly forgotten. Breckenridge [1] measured these parameters from 10^2 to 10^8 Hz for KBr at 85 °C. However, to see an effect in ε_2, it was necessary to heat-treat the sample to produce defects; this gave rise to extrinsic absorption, which is not of particular interest here, and these numbers are not tabulated. The low-frequency (nearly dc) dielectric constant at 85 °C was found to be 4.90, which yields $n = 2.21$, in agreement with higher frequency, room-temperature values cited in Table I.

For somewhat higher frequencies, at 9.8, 35.4 and 116 GHz, Owens [2] has measured the capacity at 25 °C and cited several other values by other workers. These values of ε_1 and ε_2 along with far-IR values of Genzel *et al.* [3] and Stolen and Dransfeld [4] have been used by Sparks *et al.* [5] in a model invoking two-phonon difference processes in the range 0.5 to 33 cm^{-1}. We emphasize the calculated results for 293 K, since these fit the measured values over most of the range to better than ±50% (the largest deviation between theory and experiment); we list some other values also. Genzel *et al.* did not specify room temperature for their grating-spectrometer transmission measurements; Stolen and Dransfeld made

transmission measurements with a grating spectrometer at three wavelengths (320, 500, and 900 μm) as a function of temperature from 15 to 420 K. Samples were presumably mechanically polished with conventional grits. Quality of surface is usually not an issue at these long wavelengths.

The spectral region 20 to 240 cm^{-1} has been covered by Johnson and Bell [6] using asymmetric Fourier-transform spectroscopy. This technique yielded the phase and amplitude of the reflectivity directly with no need for Kramers–Kronig analysis or a Lorentz-oscillator-model fit. The reststrahlen minimum was measured to be 0.0008, indicating little or no polishing damage. Resolution was 2 cm^{-1}. Sample temperature was 300 K. Shoulders on the low- and high-frequency sides of the transverse optical phonon frequency are due to difference and sum phonon absorption bands, respectively. We have read graphs to obtain n and k.

For the region 250 to 700 cm^{-1} Deutsch [7] has collected the absorption coefficient α from several sources all more or less at room temperature. Transmission measurements of slab samples were used in all cases. We have read an experimental curve to obtain α and converted to k with the equation $k = \alpha\lambda/4\pi$. McGill *et al.* [8] have developed a model for multiphonon absorption and used it to fit these experimental data.

Laser calorimetry has been performed in the CO_2-laser region by at least two groups [9, 10]. The temperature rise is measured with thermocouples upon irradiation of the sample with a specific laser wavelength. The technique is very sensitive and can be used to distinguish between surface absorption and bulk absorption. Surface absorption can occur due to surface properties such as roughness and adsorption of gaseous species from the air, such as water, hydrocarbons, and so on. Bulk absorption can occur due to intrinsic processes for the purest materials or extrinsic processes due to impurity molecules (SO_4, NO_2, $HCCO_3$, and so forth) "grown" into the materials. We chose the data of Ref. [9] because they showed the smallest absorption (indicating the purest material).

In the transparent region 42 to 0.2 μm, Li [11] has collected and analyzed a great deal of n data from many references. Prism minimum deviation was the experimental method in most cases. He has fitted a Sellmeier-type equation with eleven adjustable parameters to represent the data to the fifth decimal place. The dispersion formula for 293 K is

$$n^2 = 1.39408 + \frac{0.79221\lambda^4}{\lambda^2 - (0.146)^2} + \frac{0.01981\lambda^2}{\lambda^2 - (0.173)^2}$$

$$+ \frac{0.15587\lambda^2}{\lambda^2 - (0.187)^2} + \frac{0.17673\lambda^2}{\lambda^2 - (60.61)^2} + \frac{2.06217\lambda^2}{\lambda^2 - (87.72)^2}.$$

This indicates that $\lambda_T = 87.72$ μm (114.0 cm^{-1}). For the spectral range

0.25 to 26 μm, Li states that the fourth decimal place is meaningful, with estimated uncertainties in the range 0.0001 to 0.0005. To either side the uncertainty moves to the third decimal place.

Li has also provided a temperature-dependence formula of the form

$$2n\frac{dn}{dT} = -11.61(n^2-1) + 0.39 + \frac{3.944\lambda^4}{(\lambda^2-0.03497)^2} + \frac{182.88\lambda^2}{(\lambda^2-7694.80)^2},$$

where dn/dT is in units of 10^{-5}/K and λ is in μm. Note that a 3 K difference in room temperature between labs begins to affect the fourth decimal place.

The fundamental band gap of KBr is at ~6.6 eV, and there exists much data for the region 6 to 30 eV as discussed in Refs. [12–14]. We have usually selected the more recent measurements and/or those showing more structure in the reflectivity. Although much of the data involved electron-energy-loss measurements on thin films, we have ignored this nonoptical way of determining the imaginary part of the dielectric function, because thin films are deposited and usually represent defected, polycrystalline material with voids, not bulk material. Bulk crystals cleaved in UHV are presumably the best samples for reflectivity, so synchrotron data are to be preferred.

Tomiki *et al.* measured the optical constants in the range 5.5 to 12 eV using thin plates at the band edge [13] and reflectivity and Kramers–Kronig (K–K) analysis in the opaque region at 301 K [14]. Verification of Erbach's rule at the band edge was discussed in detail [13]. Small variations between eV and cm^{-1} occur between data of Refs. [13] and [14] because we read eV from a graph in [13] and converted to cm^{-1} using 8065.48 cm^{-1}/eV, whereas Tomiki supplied original data using 8066.0 cm^{-1}/eV.

Antinori *et al.* [15] used a continuum He discharge lamp as a source of radiation in the range 13.5 to 20.5 eV. A 1-m grating spectrometer gave a resolution of better than 1.8 Å at 990 Å. Samples were cleaved in air and then put into the sample chamber, which was pumped to 10^{-5} torr. The reflectivity was K–K analyzed using the data of Rubloff [12] and Blechschmidt *et al.* [16] to cover the lower and higher energy ranges, respectively, as is required by K–K analysis. We have read the values of ε_1, ε_2 from a graph and obtained the numbers listed from the equations

$$2n^2 = \varepsilon_1 + \sqrt{\varepsilon_1^2 + \varepsilon_2^2}$$

$$2k^2 = -\varepsilon_1 + \sqrt{\varepsilon_1^2 + \varepsilon_2^2}.$$

From 13 to 31 eV we have used data of Blechschmidt *et al.* [16]. The experiments were performed at the Deutsche Elektronen-Synchrotron with a normal-incidence monochromator in a modified Wadsworth mount. Single crystals were freshly cleaved and put into the vacuum of 5×10^{-8} torr. Angle of incidence was varied from 15 to 75° for both $\parallel(p)$ and $\perp(s)$ polarizations using angles on both sides of the normal for increased accuracy. R was then used to calculate ε_1 and ε_2. We then calculated n and k from graph values of ε_1 and ε_2.

From 25 to 40 eV we have chosen the ε_1, ε_2 data of Stephan *et al.* [17]; it shows a little more detail than the data of Blechschmidt *et al.* [16] and covers a wider spectral region. The data were obtained with a grating spectrometer with an 82° angle of incidence. The source was a spark discharge with a 15 Hz rate. Sample reflectivity was measured at three angles of incidence using polarized light. We have overlapped the above UV data to give an indication of the accuracy from lab to lab.

Above 40 eV absorption decreases steadily with little structure. The data of Brown *et al.* [18] cover the range 70 to 200 eV. A grating monochromator was used at an 86° angle of incidence. The source was the Stoughton, Wisconsin, synchrotron. The films were evaporated *in situ* onto Formvar, carbon, or gold substrates whose transmission had been previously measured. Thicknesses were determined by a crystal-quartz thickness monitor.

Far above these energies the L and K absorption edges of K and Br are reached. These features occur at K(K), 3608 eV; K(Br), 13470 eV; $L_{2,3}$ (K), 295 eV; L_1 (Br), 1781 eV; L_2 (Br), 1599 eV; L_3 (Br), 1553 eV; N_1(Br), 31.3 eV. The M absorption edges for atomic K and Br are not defined in Ref. [19]. Other atomic energy states are presumably mixed into the conduction-band structure seen in k in the lower-energy region [12].

Potassium Dihydrogen Phosphate (KH_2PO_4, KDP) and Three of Its Isomorphs

DAVID F. EDWARDS and RICHARD H. WHITE
University of California
Lawrence Livermore National Laboratory
Livermore, California

Potassium dihydrogen phosphate (KDP) is perhaps the best known, most extensively studied, and most widely used crystal in laser technology. Crystals of KDP are used for frequency-upconversion operation in high-power laser systems. At the present time the NOVA laser at Lawrence Livermore National Laboratory uses KDP crystals for upconversion from the fundamental wavelength, 1.053 μm, to the second, third, and fourth harmonics, 0.527 μm, 0.351 μm, and 0.263 μm, respectively. KDP is also the primary nonlinear optical material being used at the major laser facilities in France, Great Britain, Japan, China, and the Soviet Union. Ammonium dihydrogen phosphate (ADP) and the deuterated crystals (labeled D*) AD*P and KD*P have also found use in state-of-the-art nonlinear optical devices.

For each application of these nonlinear crystals, a precise knowledge is required of the crystal's refractive index as a function of wavelength. In addition, crystal temperature has a sensitive effect on the indices within the precision range of interest. The first precise measurement of the indices of refraction of KDP and ADP for a broad wavelength range was that of Zernike [1]. He measured the indices at 25 wavelengths between 2138 Å and 1.529 μm and at 24.8°±0.2 °C. He reports his indices to be accurate to at least $\pm 3 \times 10^{-5}$. Zernike used the method of known incidence used by Rydberg [2] and Tilton *et al.* [3]. For this method a prism of the material to be measured is inserted into a Littrow-type mount monochromator. The deviation is measured for different wavelengths by measuring the angle over which the Littrow mirror had to be rotated to pass a particular wavelength to the exit slit. More recently, Kirby and DeShazer [4] reported the index measurements for KDP, KD*P, ADP, AD*P and

ISBN 0-12-544422-2

several other nonlinear crystals isomorphic to KDP. Their measurements were at 16 wavelengths from 4046 Å to 1.06 μm and a sample temperature of 33.0°±0.4 °C. This slightly elevated temperature was used to remove any absorbed water vapor on the crystal faces owing to the hygroscopic nature of these crystals. The method of minimum deviation [5] was used to measure the indices. For the deuterated crystals the index values depend on the deuterium concentration. The KD*P and AD*P crystals of Kirby and DeShazer had 96% deuterium replacement for hydrogen. Phillips [6] and Yamazaki and Ogawa [7] report indices for partially deuterated (about 90%) KD*P.

Kirby and DeShazer show that the index values vary from about 6×10^{-5} to 60×10^{-5} in the visible region for KDP crystals from different crystal growers. They correlated these differences with deviations in the crystal-lattice parameters and speculate that crystalline defects incorporated during the crystal-growth process are the cause of the lattice-parameter variations.

The measured values of Zernike [1] and Kirby and DeShazer [4] were fit separately to both a Herzberger-type and a modified Sellmeier-type dispersion formula. These two measurements ([1] and [4]) were made at slightly different temperatures. The importance of the index sensitivity to temperature is the reason for reporting both fits. Given in Tables I–IV and plotted in Figs. 1–4 are the calculated indices of refraction for KDP, ADP, KD*P, and AD*P, respectively. The reported indices of other authors were not used in these fits for several reasons, including poorly defined sample temperatures, lack of precision, or untabulated data that could not be accurately read from their curves [6–9].

The Herzberger-type dispersion formula is [10]

$$n = A + BL + CL^2 + D\lambda^2 + E\lambda^4,$$

where $L = 1/(\lambda^2 - 2.80\times10^6)$ with λ in angstroms. As explained by Herzberger, the 2.80×10^6 is the square of the mean asymptote for the short-wavelength abrupt increase in the index for 15 materials (KDP, KD*P, ADP, and AD*P not included). The coefficients, evaluated by least squares, are given in Table V. Zernike did not measure deuterated samples so no coefficients are listed for KD*P or AD*P at 24.8 °C. The RMS errors between the measured values and the dispersion-formula calculated indices are given in the fourth column. These errors (%) range from about 2×10^{-5} to 4×10^{-4}.

The data of Zernike and of Kirby and DeShazer were also independently fit to a modified Sellmeier-type dispersion formula for the convenience of the reader. These Sellmeier values are not tabulated here. The modified Sellmeier-type formula used here is not the same as introduced by Zernike

[1] and used by Kirby and DeShazer [4]. Our dispersion formula is

$$n^2 = 1 + A/(\lambda^2 - B) + C\lambda^2/(\lambda^2 - D),$$

where the wavelength λ is in angstroms. This form is preferred to that of Zernike because of the rate and uniqueness of convergence of the regressive fit. The Zernike modified formula will converge to a local minimum depending on the initial guesses for the coefficients, and does not result in a unique coefficient set. This nonuniqueness of the Zernike modified formula can also be demonstrated by straightforward algebra. Zernike's modified formula is of the form

$$n^2 = A + B/(\lambda^2 - C) + D\lambda^2/(\lambda^2 - E).$$

Adding and subtracting $(-B/C + D)$ results in a formula of identical form but with the new coefficients in terms of the original coefficients.

The coefficient sets for our modified Sellmeier-type dispersion formula are given in Table VI. As before, coefficients are given for both 33.0° and 24.8 °C to demonstrate the temperature sensitivity of the indices. No data are given for the deuterated crystals at 24.8 °C because Zernike did not include these crystals in his measurements. The RMS error between the measured indices and the calculated values is given in Column 4, Table V. Overall, the fits for the two temperatures are within a few places in the fourth decimal with the one exception.

A comparison of the Zernike data at 24.8 °C with those of Kirby and DeShazer at 33.0 °C shows that the indices are sensitively dependent on sample temperature. The temperature dependence of the indices for KDP, KD*P, and ADP have been measured by several groups. Phillips [6] measured the indices of KDP, KD*P, and ADP at about nine wavelengths and three or four temperatures between the Curie point and room temperature. He estimates the data accuracy to be $\pm 10^{-4}$. Yamazaki and Ogawa [7] measured the temperature dependence for three wavelengths for these same materials and over the same temperature range as Phillips, and their results are similar. Likewise, similar results are reported by Onaka and Kawamura [8] for KDP, Onaka and Takeda [8] for ADP, and Barnes *et al.* [9] for KDP, KD*P, and ADP. An intercomparison of the predicted indices of Refs. [6–9] with the measured values of Refs. [1, 4] for small temperature intervals shows an internal consistency of 10^{-4} or smaller with the data of Onaka and Kawamura [8] having the greatest discrepancy. Phillips [6] has given the following empirical equation for the temperature change of index:

$$\Delta n = (n^2 + an + b)c(298 - T),$$

where T is the temperature in K. The values of the coefficients are given in Table VII.

Davis and Vedam [11] have measured the pressure dependence of the refractive indices at 5893 Å for KDP and ADP under hydrostatic conditions to 7 kbars. Both the ordinary and extraordinary indices were found to vary linearly with pressure for both materials. From their data the slopes of the index change with pressure curves are $+1.55 \times 10^3$/kbar and $+1.31 \times 10^3$/kbar for the KDP ordinary and extraordinary values, respectively. For ADP the values are 1.43×10^3/kbar and 1.12×10^3/kbar. They measured no deuterated crystals.

The reststrahlen spectrum of KDP and some of its isomorphs have been studied by several groups with emphasis on the low-frequency vibrational modes, one of which goes soft as the temperature is lowered below room temperature to the Curie temperature [12–22]. The coupling of these modes produces broad reflection peaks, which have been fitted with various models. Many of these references do not give information on all four parameters, ε' and ε'' for $(\mathbf{E} \perp c)$ and $(\mathbf{E} \| c)$, and the notation varies ($\| c \equiv c$, $\perp c \equiv a$). Often the graphs are too small to read. Raman-scattering studies of the phonon modes also abound [23–27].

In lieu of an extended study of this complicated IR spectral region to sort out the n and k values, we have listed in Table VIII various references with some pertinent information and leave it to the reader to examine the data directly. Much information about KDP and some of its isomorphs is given in Ref. [28].

Sodium Fluoride (NaF)

I. OHLÍDAL and K. NAVRÁTIL
Department of Solid State Physics
Faculty of Science
Masaryk University Brno
Kotlářská 2
611 37 Brno, Czechoslovakia

The room-temperature values of the refractive index n and the extinction coefficient k tabulated here (see Table I and Fig. 1) were obtained from the following works: the 0.166 μm (7.56 eV) to 0.101 μm (12.4 eV) results are from the paper of Fabre *et al.* [1]; the 0.225 μm (5.5 eV) to 0.124 μm (10.0 eV) results are from the paper of Tomiki and Miyata [2]; the 2 μm (0.62 eV) to 0.25 μm (4.96 eV) values are from Navrátil and Ohlídal's measurements [3]; the 0.578 μm (2.15 eV) to 0.186 μm (6.7 eV) results are from the paper of Kublitzky [4]; the 1.1 μm (1.13 eV) to 0.238 μm (5.2 eV) values are presented by Harting [5]; the 24 μm (0.05 eV) to 0.546 μm (2.3 eV) data are from Hohls's measurements [6] and the 111.1 μm (90 cm^{-1}) to 21.1 μm (475 cm^{-1}) values were published by Pai *et al.* [7].

The values of n and k presented by Fabre *et al.* [1] were obtained by interpreting spectral dependences of the reflectance of NaF films corresponding to different thicknesses. These films were produced by vacuum evaporation using resistively heated sources. The substrates of the NaF films studied were formed by glass plates. In the formula for the reflectance, a roughness of the upper boundaries of the NaF films analyzed was handled in a certain way [1, 8], such that, in the spectral region mentioned, the influence of this roughness was eliminated in determining n and k for these films, at least in a first approximation. Absorption is caused by excitons in this region.

Tomiki and Miyata [2] determined the values of n and k characterizing sodium-fluoride plates by means of the values of the transmittance and the reflectance of these plates measured in the region $0.225\ \mu m \geq \lambda \geq 0.124\ \mu m$. In this region Tomiki and Miyata's values of n agree in a satisfactory way with those presented by Fabre *et al.* [1] for the NaF thin films (see Table I).

However, in this region there are substantial differences between the values of k presented by Tomiki and Miyata and by Fabre *et al.* One can expect that the values of k determined by Tomiki and Miyata are more accurate than those determined by Fabre *et al.* The values of k characterizing the NaF film studied by Fabre *et al.* are apparently too great. These values are probably influenced by the light scattering caused by volume inhomogeneities not included in the formula for the reflectance of these films (for example, this scattering can be caused by microcrystals [1]). Moreover, the other structure defects can strongly affect the correctness of the data presented by Fabre *et al.* [1] (for example, some impurities occurring in the NaF films). These effects can evidently increase the values of k characterizing thin films.

In the region $2\,\mu m \geq \lambda \geq 0.25\,\mu m$, the values of the refractive index n were determined using the spectral dependences of the reflectance of the NaF films evaporated onto glass and single-crystal silicon substrates. In this region the NaF films are transparent, and therefore the thickness of these films was found by the Fizeau method, and the values of n were evaluated from the reflectance measured at the wavelengths of interest (the thickness of the NaF films was about 100 nm). The errors in n are ± 0.008 over the entire region mentioned. There is relatively good coincidence between the refractive index data of Fabre *et al.* [1] and Navrátil and Ohlídal [3]. (One can expect reasonable agreement of both sets of data after an extrapolation of the data of Fabre *et al.* [1] to longer wavelengths using a suitable dispersion formula; see Table I.) In Table I the value of n given by Pulker [9] for NaF films at the wavelength of $0.55\,\mu m$ is also listed. Taking into account the errors, we find that the values of n published by Pulker [9] agree very well with those determined by Navrátil and Ohlídal [3].

Kublitzky [4] measured the values of n characterizing sodium-fluoride prisms by the method of minimum deviation at selected wavelengths in the spectral region $0.578\,\mu m \geq \lambda \geq 0.186\,\mu m$. Harting [5] and Hohls [6] determined n by the same method in the regions $41\,\mu m \geq \lambda \geq 0.238\,\mu m$ and $10.9\,\mu m \geq \lambda \geq 0.8\,\mu m$, respectively. Moreover, in the region $19.7\,\mu m \geq \lambda \geq 8.8\,\mu m$, Hohls [6] evaluated the refractive-index data of NaF using interferometric methods based on determining positions of fringes of equal chromatic order for light reflected or transmitted by sodium-fluoride slabs. Furthermore, in the region $24\,\mu m \geq \lambda \geq 0.546\,\mu m$, Hohls determined the values of n and k for thinned plates of sodium fluoride by means of the values of the reflectance and the transmittance of these plates measured at selected wavelengths (the thickness of the thinnest plate was 0.024 mm). The thicknesses of the sodium-fluoride plates were determined independently [6].

Pai *et al.* [7] determined the spectral dependences of both n and k characterizing sodium-fluoride bulk samples using amplitude and phase-reflection measurements made by dispersive Fourier transform spectros-

copy in the region 111 μm $\geq \lambda \geq$ 21.2 μm. The errors of n and k determined in this way are dependent on wavelength. (The greatest and/or smallest errors in both n and k are equal to ± 0.56 and/or ± 0.005 at the wavelength of about 41 μm and/or 24 μm [7]). Spectral dependences of n and k in the vicinity of the maximum value of k at the wavelength $\lambda = 40.3$ μm are related to one-phonon absorption, corresponding to the TO phonon mode. The fine structure of the curve expressing the spectral dependence of n in the region 24–34 μm may be caused by multiple-phonon processes of absorption. However, a corresponding structure in k in this region is not observed (see Table I and Fig. 1). This discrepancy is probably caused by the fact that reflection techniques are not too sensitive to small changes of absorption. The structure in both the n and k curves in this region can be seen only when precision transmittance measurements of sufficiently thin NaF slabs are performed.

One can see that the values of n and k characterizing bulk NaF evaluated by the different authors at the same wavelengths agree very well (see Table I). This fact gives significant support for the correctness and reliability of the n and k values of bulk NaF presented here.

It should be also noted that the values of n describing the NaF thin films [3] in the region 2 μm $\geq \lambda \geq$ 0.25 μm are nearly identical with those characterizing bulk NaF [4–6]. This fact implies that the packing density p defined by $p = V_s/V$ (where V_s and V are the volume of the solid part of the film and the total volume of the film, respectively) is nearly equal to unity. This can be demonstrated if the value of p characterizing the NaF thin films studied [3] is calculated by means of the following formula for the mean refractive index of films with columnar structure [10–12]:

$$n = n_s p + n_o(1 - p), \tag{1}$$

where n, n_s, and n_o denote the mean refractive index, the columnar (bulk) refractive index of the film, and the refractive index of a substance filling the pores between columns. Assuming that $n_o = 1$, one obtains (using Eq. 1 and the values of n and n_s presented here) the value of $p = 0.98$. This means that the NaF films analyzed by Navrátil and Ohlídal [3] are formed by very close-packed columns [11, 13].

In conclusion, one can state that the refractive-index data summarized in this work represent the true values of n characterizing bulk NaF in the spectral regions under consideration (see Table I and Fig. 1). (In the region 0.124 μm $\geq \lambda \geq$ 0.101 μm, this conclusion is valid for the values of n determined by Fabre *et al.* [1], at least in a first approximation.) The same statement can be said for the extinction-index data, except for the region 0.124 μm $\geq \lambda \geq$ 0.101 μm. Namely, the values of k determined by Fabre *et al.* [1] in the region 0.166 μm $\geq \lambda \geq$ 0.101 μm can serve only as rough

information concerning the form of the spectral dependence of k of bulk NaF.

It should be noted that the refractive-index data corresponding to the region of transparency of NaF were also presented by Li [14].

Strontium Titanate ($SrTiO_3$)

FRANÇOIS GERVAIS
Centre de Recherches sur la Physique des Hautes Températures
Centre National de la Recherche Scientifique
45071 Orléans, France

Strontium titanate crystallizes in the cubic perovskite structure. Optical properties are therefore isotropic. Strontium titanate behaves like a ferroelectric material in the paraelectric phase. This property is referred to as *incipient ferroelectric*. The hypothetical Curie temperature would take place just below the absolute-zero temperature. As a result, the dielectric constant is strongly dependent on temperature and increases by a factor as large as 10 when the sample is cooled from room temperature to liquid-helium temperature [1]. Since the dielectric constant is the extrapolation down to zero frequency of the dielectric response, which itself is the square of the complex refractive index, optical constants also vary with temperature, but mainly in the far infrared. In addition, a phase transition related to alternate tilt of oxygen octahedra, which results in the formation of a tetragonal structure, takes place upon cooling below 105 K. The temperature dependence of data related to optical constants has been studied in various references; see Refs. [2, 3] for the UV range, Refs. [4, 5] in the visible and Refs. [6, 7] in the infrared.

Doping with Nb^{5+} or reduction of strontium titanate confers semiconducting properties to the material. Then the absorption related to free carriers may drastically modify the optical constants in the infrared depending on doping level [8]. Note also that heavily doped *n*-type strontium titanate has been reported to become a superconductor below 0.7 K [9].

All data compiled in Table I and Fig. 1 were obtained by measurements on undoped single crystals at room temperature. It should also be noted that in the infrared range, the reflectivity measurements performed on a sintered and polished strontium-titanate ceramic sample are practically indistinguishable from those performed on a single crystal [10], so that data compiled here, all obtained from studies on single crystals, are valid for ceramics also.

Reflectivity measurements in the ultraviolet energy range have been performed by various authors [11–14]. Among those studies, the one that

ISBN 0-12-544422-2

extends over the widest energy range is the one by Baüerle *et al.* [13], thus allowing a Kramers–Kronig analysis of reflectivity data. Results of such an analysis are reported in Ref. [13] and reproduced in Table I. No n, k data were deduced from the experiments in other papers, but reflectance spectra shown in the three papers are in good agreement. Measurements of Ref. [13] were performed with the polarized synchrotron light from the storage ring DORIS at Hamburg coupled with a high-resolution monochromator.

The index of refraction in the transparent region is reported in Ref. [11] for wavelengths between 0.4 and 1.1 μm. They are in agreement with earlier measurements of Ref. [15], which were limited to a narrower wavelength range. Results of Ref. [11] determined by the angle-of-minimum-deviation method are given in Table I.

Early infrared reflectivity measurements of strontium titanate were reported by Barker and Tinkham [6]. The resolution of their measurement was not sufficient to detect a narrow infrared band observed three months later by Spitzer *et al.* [16] near 175 cm^{-1}, also with a prism monochromator. Spitzer *et al.* showed the failure of the usual dielectric function model,

$$\varepsilon = \varepsilon_\infty + \sum_j \Delta\varepsilon_j \frac{\Omega_{j\mathrm{TO}}^2}{\Omega_{j\mathrm{TO}}^2 - \omega^2 + i\gamma_{j\mathrm{TO}}\omega}, \tag{1}$$

expressed in terms of a sum over all the polar modes of the contributions of individual transverse optic modes, to fit the spectrum of strontium titanate. Later, Barker and Hopfield [17] introduced a mode-coupling formalism to fit the spectra of such highly polar incipient ferroelectric or ferroelectric crystals. An alternative model based on the factorized form of the dielectric response,

$$\varepsilon = \varepsilon_\infty \prod_j \frac{\Omega_{j\mathrm{LO}}^2 - \omega^2 + i\gamma_{j\mathrm{LO}}\omega}{\Omega_{j\mathrm{TO}}^2 - \omega^2 + i\gamma_{j\mathrm{TO}}\omega}, \tag{2}$$

was proposed subsequently [7] to palliate the weakness of the classical dielectric constant formula (Eq. 1) in such cases. The authors of this analysis also remeasured the infrared reflectivity spectrum with a modern Fourier-transform wide-band infrared spectrometer. Results for n and k obtained from a Kramers–Kronig analysis of data of Ref. [16] and from Ref. [7] by best fit of Eq. 2 to reflectivity data are compared in Table I. Both sets of data agree reasonably well.

Thorium Fluoride (ThF_4)

I. OHLÍDAL and K. NAVRÁTIL
Department of Solid State Physics
Faculty of Science
Masaryk University
Kotlářská 2
611 37 Brno, Czechoslovakia

Thorium fluoride possesses desirable optical properties including a broad range of transparency from the UV (0.2 μm) to the mid-IR (12 μm) regions, and low dispersion and low refractive index in the visible. Therefore, this material is widely used to form low-refractive-index thin films in non-absorbing multilayer systems employed for interference devices. For example, ThF_4 thin films together with ZnS thin films are utilized for producing interference coatings which can be used as broad-band laser mirrors in the visible [1].

ThF_4 is usually evaporated using resistively heated sources. Such ThF_4 thin films are soft, chemically very stable, and exhibit medium tensile stress [2]. The structure of the ThF_4 films was examined only by Heitmann and Ritter [3] using X-ray analysis. They found that these films were amorphous. However, X-ray analysis is less sensitive for the structure analysis of polycrystalline solids and thin films than methods of the electron analysis [4]. By means of X-ray analysis it is difficult, if not impossible, to reveal microcrystals whose linear dimensions are smaller than about 5 nm [4]. Thus, the results of X-ray analysis obtained by Heitmann and Ritter [3] show that the studied ThF_4 films can be amorphous or polycrystalline with very small microcrystals (smaller than about 5 nm in the linear dimensions). These films have optical properties, which are dependent on a number of effects:

(1) the columnar structure, and hence, the distribution of voids or low-density regions in the film

(2) the orientation of these columns with respect to the substrate normal and their dimensions

(3) environmental stability connected with capillary condensation taking place into the open voids (sometimes called pores)

(4) the form of the columns and their variation with thickness, implying inhomogeneity of the film
(5) stress in the film, and hence, birefrigence and inhomogeneity
(6) surface roughness of the upper boundary of the film.

The most important of these effects is the columnar structure. The other effects are implied in principle by this structure (except the existence of the stress in the film). Thus, to describe in a true way, the optical properties of the ThF_4 and similar films, one has to express the optical constants of these films with formulas representing their columnar structure in a satisfactory manner. So far, this task has been solved primarily by using suitable formulas for the optical constants of the columnar films based on effective-medium theory [5–8]. For example, within this theory the following formula is often employed for evaluating the mean refractive index $\bar{n}$ of the film considered:

$$p\frac{n_s^2-\bar{n}^2}{n_s^2+2\bar{n}^2}+(1-p)\frac{n_v^2-\bar{n}^2}{n_v^2+2\bar{n}^2}=0, \tag{1}$$

where n_s and n_v denote the refractive indices of the columns and voids, respectively. p is the packing density defined by $p=V_s/V$, where V_s and V are the volume of the solid part of the film (columns) and the total volume of the film (including the voids), respectively. Equation 1, known as the Bruggeman [9] formula, is valid if the voids are filled with one nonabsorbing substance and the columns are formed by another nonabsorbing material. Of course, this equation can be generalized for an arbitrary number of materials forming the columns and the voids in the film [10] (for example, when the voids are partially filled with water and air).

So far, the values of the refractive index and the extinction coefficient of the ThF_4 thin films have been measured in the region $11\ \mu m \geq \lambda \geq 0.22\ \mu m$, that is, in the region of transparency of these films. The values of both optical constants of the ThF_4 films were primarily determined using an interpretation of experimental data (ellipsometric parameters, reflectance, and transmittance) based on single layers. The interpretation was performed within the framework of a model consisting of the single layer with ideally smooth and flat boundaries placed on a substrate. Furthermore, it was assumed that both the film and the substrate were formed by homogeneous and isotropic materials from the optical point of view. In this way either the mean optical constants of the films or the optical constants close to them were determined. These optical constants denoted by the symbols n (refractive index) and k (extinction coefficient) evaluated by Heitmann and Ritter [3] for the region 0.8–0.22 μm are collected in Table I and plotted in Fig. 1. Heitmann and Ritter analyzed the ThF_4 single layers

deposited by vacuum evaporation (molybdenum or platinum boat) onto quartz-glass substrates by using the values of reflectance of this system corresponding to the wavelengths λ at which the optical thicknesses of these films were equal to $m\lambda/4$ ($m = 1,3,5, \ldots$).

Table I shows that, in the visible, the refractive index of the ThF_4 thin films is roughly constant and lies in the range 1.52–1.53 (the error in the refractive indices was less than $\pm 1\%$). The values of n characterizing vacuum-evaporated ThF_4 single layers determined by Heisen [11] are outlined in Table I as well (Heisen evaluated the values of n for wedge-shaped ThF_4 films using an interferometric method for $\lambda = 0.546$ and 0.4358 μm). There is relatively good agreement between the values of n presented by Heitmann and Ritter [3] and Heisen [11] even when there were certain differences in preparation of the ThF_4 films. The values of k corresponding to the near-UV, the visible, and the near-IR regions can be considered to be zero for the majority of applications of ThF_4 films in optics. However, if multilayer systems with a great number of films are produced (for example, the mirrors for lasers with more than 30 films), the optical losses resulting from absorption and scattering must be considered inside of every film of this system [12]. Very small absorption losses in ThF_4 films can be measured. The method of Ahrens *et al.* [13] (based on measuring the temperature change caused by absorption of light by the film using a thin, gold-film resistance thermometer) was used to determine the values of the absorption coefficient for the wavelengths of 0.515 and 1.06 μm [12]. The values of the absorption coefficient determined by Pulker yield the following values of the extinction coefficient: $k = 3.3 \times 10^{-5}$ and 1.3×10^{-6} for $\lambda = 0.515$ and 1.06 μm, respectively [12].

Mouchart *et al.* [14] determined the values of both the refractive index and the extinction coefficient characterizing ThF_4 films in the mid-IR region $11\ \mu m \geq \lambda \geq 4\ \mu m$ by means of the spectral dependences of the transmittance (the ThF_4 films were deposited onto germanium substrates using electron bombardment in vacuum). They employed the method of Manifacier *et al.* [15] based on the use of the envelopes of the interference maxima and minima in the spectral dependences of the transmittance, since the ThF_4 films under investigation were relatively thick (2.2–4.9 μm). These authors also determined the coefficients of the following dispersion relations expressing the spectral dependences of n and k in the region considered:

$$n(\lambda) = A_0 + \frac{A_1}{\lambda} + \frac{A_2}{\lambda^2}, \tag{2}$$

$$k(\lambda) = B_0 + B_1\lambda + B_2\lambda^2, \tag{3}$$

The coefficients are as follows [14]: $A_0 = 1.118$, $A_1 = 2.46\ \mu m$, $A_2 = -$

2.98 μm^2, $B_0 = 0.00189$, $B_1 = -0.00015$ μm^{-1}, and $B_2 = 0.00001$ μm^{-2}. For the region 12 μm$\geq\lambda\geq$4 μm, the values of n and k calculated by Eqs. 2 and 3 are summarized in Table I and Fig. 1. It is interesting to note that the values of n for ThF_4 films placed on ZnS substrates as determined ellipsometrically at $\lambda = 10.6$ μm by Pedinoff *et al.* [16] agree very well with those found by Mouchart *et al.* [14] at the same wavelength, if the errors of n are taken into account (Pedinoff *et al.* determined the values of n with the accuracy of ±1.5%).

Kim and Vedam [17] determined the spectral dependence of the refractive index of ThF_4 films deposited on vitreous silica substrates using spectroscopic ellipsometry in the region 0.9–0.25 μm. These authors expressed the dispersion of the refractive index n by the formula

$$n^2(\lambda) = A + \frac{B\lambda^2}{\lambda^2 - \lambda_0^2}, \tag{4}$$

which represents a first approximation of the well-known Sellmeier dispersion equation,

$$n^2(\lambda) - 1 = a + \sum_{j=1} \frac{b_j\lambda^2}{\lambda^2 - \lambda_j^2}. \tag{5}$$

a, b_j, λ_j, A, B, and λ_o are constants (λ_o is the wavelength of the Sellmeier oscillator).

They used a three-layer model for interpreting the spectral dependences of the ellipsometric parameters [17]. Within the framework of this model, the columnar structure was assumed for both the upper and the lower layers (see Eq. 1), and therefore, eight parameters were needed. (That is, the values of A, B, and λ_o, the thicknesses characterizing all three layers, and the packing density of the upper and the lower layers must be evaluated.) From the values of A, B, and λ_o found, that is, $A = 1.665 \pm 0.005$, $B = 0.715 \pm 0.004$, and $\lambda_o = (0.149 \pm 0.001)$ μm [17], the values of n characterizing the ThF_4 films were calculated using Eq. 4 in the region 2 μm$\geq\lambda\geq$0.22 μm (see Table I and Fig. 1). The errors of these values are about ±0.005. The refractive index n determined in this way represents the columnar refractive index n_s of ThF_4 films.

Thus, the values of n found by Kim and Vedam [17] can be considered as those for the bulk refractive index of thorium fluoride. This statement is supported by the fact that the values of n determined using the results of Kim and Vedam are greater than those presented by Heitmann and Ritter at all wavelengths (see Table I). It should be noted that a spectral

dependence of the refractive index of a bulk sample of this material has not been measured yet. This means that the values of n presented by Kim and Vedam represent the best ones characterizing thorium fluoride in the region $2\ \mu m \geq \lambda \geq 0.22\ \mu m$ at present. However, the three-layer model of the ThF_4 films used by Kim and Vedam can be improved, so that even better values of n for ThF_4 can be obtained by reanalyzing the ellipsometric data of the ThF_4 films.

Dielectric [18] and metallic [19] thin films prepared by the ion-assisted deposition (IAD) process exhibit improved optical and mechanical properties; the environmental stability of these coatings is also improved. These improvements are caused by increasing the packing density of the films. The effect of IAD on the optical properties of the ThF_4 films deposited using a resistively heated source on unheated fused silica and sapphire substrates was examined also [20]. Bombardment of the growing ThF_4 films with 300 eV Ar ions was carried out during deposition. When the growing ThF_4 films were bombarded with an ion current density of $70\ \mu A/cm^2$, the value of n (the mean refractive index) was 1.56, compared with 1.53 for the unbombarded samples at the wavelength of $0.6\ \mu m$ [20]. The bombarded ThF_4 films exhibited high resistivity against the influence of moisture, which was demonstrated by very low absorption of these films in the water band near $3\ \mu m$. This fact implies that the packing density is close to unity. The refractive index value of 1.56 at $\lambda = 0.6\ \mu m$ agrees very well with that determined by Kim and Vedam [17], which also supports the conclusion concerning the good quality of Kim and Vedam's data.

Table I shows that the refractive-index values presented by Mouchart *et al.* [14] for the region $11\ \mu m \geq \lambda \geq 4\ \mu m$ do not correspond to those of Heitmann and Ritter [3] and Kim and Vedam [17]. Namely, the values of n found by Mouchart *et al.* at $\lambda = 4\ \mu m$ and the wavelengths close to that are relatively high compared with the refractive-index values published for the wavelengths of the visible in Refs. [3] and [17]. Moreover, dispersion of n presented by Mouchart *et al.* is rather pronounced. (An extrapolation of the data of Mouchart *et al.* to the visible and near-UV region gives values of n substantially higher than those presented in Refs. [3] and [17]). These discrepancies may be explained by the fact that the films analyzed by Mouchart *et al.* [14] were probably formed with a mixture of thorium fluoride and thorium oxide. For example, ThO_2 films are characterized by considerably higher values of the refractive index than the ThF_4 films in the visible and near-UV region: the values of n characterizing the ThO_2 films lie in the interval 1.75–1.9 from the visible to the near UV region [21]. Other, more reliable data of ThF_4 films are not available in the mid-IR region at present. Values of n and k of ThF_4 films for the far-IR region have not been presented yet, since spectrophotometric or Raman measurements have not been performed in this region (that is, optical-phonon frequencies of ThF_4 are not known).

In conclusion, it should be noted that thorium and its compounds are radioactive. In general, no risk of external radiation damage is present. However, incorporation of thorium compounds into the human organism does present danger. Recommended maximum permissible limits for thorium compounds in the body are outlined in Ref. [3].

One could easily prepare a list of several hundred primary references to the scientific literature on spectral measurements of the optical properties of water and compilations of water's refractive index and absorption coefficient. In this critique, however, we only highlight such activities during the past century. Readers interested in more detail should consult bibliographies in the references cited here. To those who contributed to the scientific literature on the optical properties of water and are not explicitly acknowledged here, we apologize. We conclude the critique with two of our previously unpublished compilations of n and k for water.

In 1892, Rubens [1] presented refractometer measurements of the refractive index $n(\lambda)$ of water to a long-wavelength limit of 1.256 μm. These measurements of $n(\lambda)$ were extended to a new long-wavelength limit of 2.327 μm by Seegert's [2] doctoral work in 1908. In 1908 and 1909, Rubens and Ladenberg [3] published their measurements of the reflectance and absorption spectra, and determined what was later discovered to be incorrect dispersion $n(\lambda)$ of water out to a wavelength of 18 μm. Others who measured the infrared reflectance spectrum of water in 1906, 1915, 1918, and 1931, respectively, were Pfund [4], Gehrts [5], Brieger [6], and Weingeroff [7]. General reviews of the infrared absorption spectrum of water were published in 1917, 1929, 1930, and 1934 by Fowle [8], Lecompte [9], Schaefer and Matossi [10], and Dawson and Hulburt [11], respectively. Compilations of the optical properties of water were published in 1929 by Becquerel and Rossignol [12], and in 1940 by Dorsey [13].

One can gain a historical and technical perspective from Dorsey's thorough compilation of water's optical properties. He presented data, gleaned from about 320 references, that spanned the spectral range from low frequency (dielectric constants) to the X-ray region (absorption coefficients). For example, Dorsey's Table 137 provides values for $n(\lambda)$ in the

ISBN 0-12-544422-2

wavelength range 0.154 nm–11 mm. For the visible and ultraviolet regions, Dorsey reviewed several dispersion relations for the refractive index of water at temperatures in the range of 0–80 °C. Of particular interest to Dorsey were the data of Martens [14], Duclaux and Jeantet [15], Chéneveau [16], and Tilton and Taylor [17].

Among those who also published works prior to 1941 on the optical properties of water were Paschen [18], 1894; Coblentz [19], 1905, 1906, and 1911; Goldhammer [20], 1913; Collins [21], 1922 and 1939; Plyler [22], 1924; Dreisch [23], 1924; Hulburt [24], 1928; Cartwright [25], 1935; Williams *et al.* [26], 1936; and Fox and Martin [27], 1940.

Centeno's [28] tabulation in 1941 of n and k for water, and the compilation previously published by Dorsey in 1940, were benchmarks for the future of such activity and were the standard of such compilations for nearly three decades. Centeno gleaned data from 59 articles, including all those previously noted here, to determine n and k for water in the 0.1151–18 μm and 1–18 μm wavelength regions, respectively. Centeno's values of $n(\lambda)$ in the ultraviolet, visible, and near infrared were from Refs. [13], [16], and [17]. Centeno corrected the infrared absorption spectrum of a 90% water and 10% glycerin mixture previously measured in 1909 by Rubens and Ladenburg [3], to obtain the absorption and extinction coefficients $\alpha(\lambda) = 4\pi k(\lambda)/\lambda$ and $k(\lambda)$ of water. Possessing corrected values for $k(\lambda)$ and the normal-incidence infrared reflectance spectrum $R(\lambda)$ [3] of water, he determined $n(\lambda)$ by use of

$$R = \frac{[(n-1)^2 + k^2]}{[(n+1)^2 + k^2]}.$$

The scientific literature on the optical properties of water fell silent through the 1940s. During the 1950s the following articles on the absorption and reflectance of water appeared in the literature: studying absorption were Curcio and Petty [29], 1951; Blout and Lenormant [30], 1953; Plyler and Aquista [31], 1954; Adams and Katz [32], Ceccaldi *et al.* [33], and Potts and Wright [34], 1956; Hyman *et al.* [35], 1957; Bocharov and Krutikov [36], and Waggener [37], 1958; and Goulden [38], 1959; Kislovskii [39], 1959, studied reflectance.

Kislovskii [39], who concluded his paper with a dateline of Christmas Day, 1958, measured the reflectance spectrum and determined the first fairly reliable values of n and k of water in the 2.1–3.4 μm wavelength range. He used semiempirical conceptual models to compute n in the 182.9 nm–1000 Km wavelength region. He also used the conceptual models to calculate k in the 2.0 μm–1000 Km wavelength region. Kislovskii's determinations of k, the measurements of $\alpha(\lambda)$ by Curcio and Petty [29] in the 0.7–2.5 μm wavelength region, and similar measurements of $\alpha(\lambda)$ by

Plyler and Aquista [31] in the 2–42 μm wavelength region, provided the standard values of k for the next six to nine years. A systematic error, however, was later discovered in the work of Plyler and Aquista. The error was corrected in part by measurement and publication of "Absolute Absorption Coefficients of Liquid Water at 2.95 μm, 4.7 μm, and 6.1 μm" by Plyler and Griff [40] in 1965.

The advent of the space age in 1957, the development of space technology in the 1960s and 1970s, and the consequent new opportunities for remote sensing of planetary atmospheres and surfaces created renewed interest in the optical properties of natural mineral materials. On Earth, water is a ubiquitous substance, and it was thus essential that some members of the scientific community again devote their interest to the optical properties of water. For the past three decades, an accurate compilation of $N = n + ik$ of liquid water and ice over the broadest possible range of frequency ν or wavelength λ has thus been a topic of considerable interest, particularly to those engaged in the endeavor and to those who used and continue to use the data in a host of varying theoretical constructs.

During the 1960s the following articles on the optical properties of water appeared in the literature: McDonald [41], 1960; Ackermann [42], 1961; Stanevich and Yaroslavskii [43], 1961; Bayly *et al.* [44], 1963; Kondratyev *et al.* [45], 1964; Plyler and Griff [40], 1965; Thompson [46], 1965; Bagdade and Tinkham [47], 1965; Draegert *et al.* [48], 1966; and Kondratyev [49], 1969, all studied absorption. Studying reflectance were McAlister [50], 1964; Pontier and Dechambenoy [51], 1965–1966; Painter *et al.* [52], 1968–1969; Querry *et al.* [53], 1969; and Zolotarev *et al.* [54], 1969.

Pontier and Dechambenoy [51] measured reflectance spectra of water for angles of incidence of 0 degrees (1965), and 50 and 60 degrees (1966), in the 1–38 μm and 1–28 μm regions, respectively. They also measured the absorption spectrum $\alpha(\lambda)$ in the 1–40 μm wavelength region (1966). The reflectance and absorption spectra, and the appropriate Fresnel equations, were used to determine n and k throughout the 1–40 μm wavelength region.

In 1968, Irvine and Pollack [55] published a more extensive tabulation of n and k for water and ice in the 0.2–200 μm wavelength region. Although they seemed to have overlooked the work by Pontier and Dechambenoy [51], Irvine and Pollack considered data from references [21, 23, 25, 27–48] to prepare their tabulation of the optical constants of water.

In 1969 and 1970, Zolotarev *et al.* [54, 56] presented a tabulation of $N(\lambda)$ for the $1\text{–}1 \times 10^6$ μm wavelength region. In the 1970 paper [56], they used four methods to determine n and k: measurements of absorption, reflectance, internal reflectance spectra, and Kramers–Kronig (K–K) analysis. Sources of spectral values of k used in the K–K analysis to determine n were the following:

Wavelength Region	Reference
$0.2 \leq \lambda \leq 1.0\ \mu m$	Lane and Saxton [57], 1952; Collie *et al.* [58], 1948; Gelebart and Johannin-Gillen [59], 1948;
$1.0 \leq \lambda \leq 2.0\ \mu m$	Kontratyev *et al.* [45], 1964;
$2.0 \leq \lambda \leq 40\ \mu m$	Zolotarev *et al.* [54, 56], 1969–70;
$40 \leq \lambda \leq 250\ \mu m$	Draegert *et al.* [48], 1966;
$250 \leq \lambda \leq 1000\ \mu m$	Stanevich and Yaroslavskii [43], 1961;
$l \geqslant 1000$ mm	Chamberlain *et al.* [60], 1966.

In the early 1970s several measurements were made of the optical properties of water [61–69]. In 1973, Hale and Querry [70] published a tabulation of $N(l)$ for water in the 200 nm–200 mm wavelength region based on a compilation and K–K analysis of $k(\lambda)$ to obtain $n(\lambda)$. Their compilation of $k(\lambda)$ was based on data selected from 58 references spanning 81 years of the scientific literature. Then, in 1975, Downing and Williams [71] presented a tabulation of $N(\nu)$ for the 10–5,000 cm^{-1} wave-number region, which also was based on a compilation and K–K analysis of $k(\nu)$ to determine $n(\nu)$.

In 1981, Segelstein [72] completed an extensive compilation of $k(\nu)$ for water throughout the 10^{-6} to $10^{8}\,cm^{-1}$ wave-number region. Beginning with the composite $k(\lambda)$ spectrum previously published by Hale and Querry, Segelstein incorporated data for $k(\nu)$ into the compilation for the frequency ranges and corresponding references listed below:

Wave Number Range	Reference
$0 \leq \nu \leq 5\ cm^{-1}$	Cole and Cole [73]
$5 \leq \nu \leq 500\ cm^{-1}$	Afsar and Hasted [74]
$500 \leq \nu \leq 1000\ cm^{-1}$	Robertson and Williams [62]
$3{,}300 \leq \nu \leq 4000\ cm^{-1}$	Robertson and Williams [62]
$14{,}400 \leq \nu \leq 24{,}400\ cm^{-1}$	Tam and Patel [75]
$24{,}400 \leq \nu \leq 50{,}000\ cm^{-1}$	Lenoble and Saint-Guilly [76], and Kopelevich [77]
$50{,}000 \leq \nu \leq 65{,}000\ cm^{-1}$	Painter *et al.* [78]
$65{,}000 \leq \nu \leq 200{,}000\ cm^{-1}$	Heller *et al.* [68]
$2 \times 10^{5} \leq n \leq 4.3 \times 10^{6}\ cm^{-1}$	$k(n) = An^{1.23}$ [72]
$n > 4.3 \times 10^{6}\ cm^{-1}$	$k(n) = An^{1.63}$ [72].

Segelstein used an electron sum rule to test the validity of the $k(\nu)$ spectrum. Kramers–Kronig analysis of $k(\nu)$ then provided $n(\nu)$ throughout the 10^{-3} to $10^{6}\,cm^{-1}$ wave-number region. More specific details of Segelstein's investigation of $N(\nu)$ for water will be presented elsewhere [79], but his tabulation of n and k for water is presented in Table I.

Graphical presentations of the n and k data in Table I appear in Fig. 1. The values of k in Table I are from work by several investigators, but are believed to represent n and k for water in a temperature range of 25°–35 °C.

The relatively large static dielectric constant $\varepsilon = n^2$ is due to the strong polar nature and polarizability of water. Also, the famous rotational absorption line at 1.26 cm wavelength, which hampered the development of radar in the early 1940s, occurs in water vapor and not in liquid water and is therefore not present in the data in Table I.

More recently Wieliczka *et al.* [80] used a wedge-shaped cell, which was an improved functional design of similar cells previously described by Robertson and Williams [62] and Tyler *et al.* [81], to determine accurate values of the Lambert absorption coefficient $\alpha(\nu)$ of water in the 500–8000 cm^{-1} region. Kramers–Kronig analysis of the $k(\nu)$ spectrum determined values for $n(\nu)$. Their values of n and k for water are presented in Table II. The sample was purified, deionized water. The temperature of the water was approximately 30 °C.

Yttrium Oxide (Y_2O_3)

WILLIAM J. TROPF and MICHAEL E. THOMAS
Applied Physics Laboratory
The Johns Hopkins University
Laurel, Maryland

Yttrium sesquioxide (yttria) is a body-centered cubic material with bixbyite or cubic-C structure. The space group is T_h^7 or Ia3, unit cell length is 1.0604 nm, and the unit cell has 16 formula units (80 atoms). Theoretical density is 5.033 g/cm^3, melting point is 2710 K [1], and a phase change to a hexagonal form occurs at 2640 K [1].

Yttrium ions occupy two different sites, eight octahedral sites with C_{3i} point symmetry and 24 prismatic sites with C_2 symmetry. Six oxygen ions surround each yttrium ion. Ion positions in the unit cell are known from both X-ray and neutron-diffraction measurements [2, 3].

Optical-quality, single-crystal yttria is available, typically made by the flame-fusion technique [4], and optical-quality sintered polycrystalline yttria is available in a variety of window shapes [5]. Optical-grade cubic yttria stabilized with up to 10 mole-percent thoria ("Yttralox") was previously made [6], and cubic yttria with lanthanum oxide ("lanthana-strengthened yttria") is commercially available [7, 8]. Comprehensive properties of commercial, polycrystalline yttria and lanthana-doped yttria are given in the literature [9].

Yttria is an excellent trivalent-ion host material for solid-state lasers. A variety of candidate metal-ion dopants, particularly neodymium [10], as well as many other rare-earth metals [11, 12] have been investigated.

Yttria has a band gap of approximately 6.0 eV. Several investigators have measured the optical constants from the UV through the XUV [13–16]. Earlier measurements [13, 14] used poor-quality samples and obtained results that qualitatively match recent measurements of Abramov *et al.* [15] and Tomiki *et al.* [16]. The latter measurements are considered definitive because they show the most detail, give results over the widest spectral range (3–42 eV), and agree well with the best available value of refractive index at the UV edge of the transparent region [17].

The lowest-frequency electronic feature of the yttria spectrum is an exciton peak at 6.0 eV. The peak sits on the edge of a broad resonance

ISBN 0-12-544422-2

structure extending from 6.5–15 eV at room temperature. This broad feature arises from interband transitions between the upper valence band of oxygen ($2p^6$) to the conduction band of yttrium (4d + 5s) [15, 16]. Weaker absorption in the 15–27 eV region may be caused by transitions from the upper valence band of oxygen to higher excited conduction bands of doubly ionized yttrium [16]. At energies between 27 and 35 eV, absorption is attributed to electronic transitions from the ground state ($4p^6$) of triply ionized yttrium and the $4p^54d$ and $4p^55s$ excited states, with additional transitions to the 60.6 eV ionization level of Y^{3+} postulated [16].

Tomiki *et al.* also give the temperature dependence of absorption at the UV edge of the transparent region (5.2–6.0 eV) for temperatures between 10 and 297 K and fit their measurements to an Urbach rule formulation

$$\alpha(E, T) = \alpha_0 \times \exp(-\sigma_s(T)(E_0 - E)/kT), \tag{1a}$$

where

$$\sigma_s(T) = \sigma_{s0} \times (2kT/E_{s0}) \tanh(E_{s0}/2kT). \tag{1b}$$

The constants of Eq. 1 are $\alpha_0 = 8.222 \times 10^6\ \text{cm}^{-1}$, $E_0 = 6.080$ eV, $\sigma_{s0} = 0.688$, and $E_{s0} = 0.0186$ eV. DeShazer *et al.* [18] report higher absorption values, and Nigara [17] gives even higher values.

Refractive-index data for the visible and IR transparent region of yttria are given in several sources. Wickersheim and LaFever [4] reported an index of refraction between 1.91 and 1.95 for yttria and mixed yttria–lanthana crystals. The most comprehensive data are provided by Nigara [17], who measured the index of crystals from 0.22–12 μm using different methods. His data were fitted to a Sellmeier-type dispersion relationship of the form

$$n^2 - 1 = \frac{13.4 \times 10^9}{(72{,}100)^2 - \nu^2} + \frac{7.48 \times 10^5}{(436)^2 - \nu^2}, \tag{2}$$

where ν is the frequency in wave numbers. This is the only available dispersion information for bulk yttria. Equation 2 represents electronic resonances at 72,100 cm^{-1} (8.9 eV) with the first term, and IR resonances at 436 cm^{-1} with the second term. These terms fall in the middle of the measured electronic transitions and lattice vibrations, respectively.

Tsukuda [19] also measured the refractive index of bulk transparent

yttria in the visible using an ellipsometry technique. His results are typically 0.5–1% below those of Nigara [17].

Smith and Baumeister [20] measured the refractive index of thin films of yttria over the 0.25–2 μm spectral range and found that the index was highly dependent on film preparation. Their measurements are significantly below those of Nigara (Eq. 2), typically by 10%, and the imaginary part of the refractive index (extinction coefficient) is much larger than is reported for bulk samples [16–18]. Thin-film refractive indices reported by Heitmann [21] are 2–3% below bulk index data [17], although more recent data by Arnon and Chou [22] also give index values 10% below that of bulk yttria.

Refractive indices of 1.92 at 0.589 μm for thoria-doped yttria (Yttralox, GE [23]) and 1.9699 at 0.546 μm for lanthana-doped yttria (an ellipsometer measurement [24]) have been reported. Equation 2 gives 1.930 and 1.937, respectively, at those two wavelengths.

Absorption in the transparent region (0.25–7 μm) is governed by impurities and defects. The most prominent absorption feature is the OH^- absorption, which occurs in a broad region between 2500 and 3500 cm^{-1} [4, 25, 26]. Various heat treatments can reduce the amount of OH^- impurity. Defect absorption in the transparent region is highly dependent on preparation environment. Several investigators show that partial pressure of oxygen is a critical factor in producing a low level of defect absorption [10, 24, 27]. The primary defect is believed to be oxygen vacancies or interstitials. When yttria is exposed to a reducing atmosphere (for example, hydrogen) at very high temperature (>2000 K), a black form of yttria is produced [28] with very high absorption in the visible. At high temperatures (>1200 K), absorption increases, likely caused by a greater concentration of oxygen vacancies and interstitials in equilibrium [24, 29].

The dominant loss mechanism in the visible and near-IR transparent region of polycrystalline yttria is scatter. Bulk scatter in polycrystalline yttria is low and decreases with increasing wavelength [8, 9, 29].

Absorption at the IR edge of transparency is dominated by multiphonon absorption. A model of yttria multiphonon absorption has been developed and confirmed with experimental data over a wide temperature range [30]. The fundamental (one-phonon) lattice vibrations occur in the 120–555 cm^{-1} spectral region. Group theory predicts the following phonon modes for yttria [31–33]:

$$\Gamma = 4E_g + 4A_g + 14F_g + 5E_u + 5A_u + 16F_u, \tag{3}$$

where all gerade modes are Raman-active, the E_u and A_u modes are inactive, and the 16 F_u modes are IR-active. Table I lists the 11 strongest modes as determined from McDevitt and Davidson [34] (modes 1–3, location only) and Thomas [35] (modes 4–11, as well as estimated widths

and strengths for modes 1–3). Thomas also gives the temperature dependence of modes 4–11 over the 290–775 K temperature range. Nigara *et al.* [32] also give parameters for modes 5–11. Bloor and Dean [33] observe an additional IR mode at 197 cm^{-1} in measurements made at 1.5 K.

Table I also lists both the transverse and longitudinal optical frequencies. The transverse optical frequencies are the mode locations; the maximum longitudinal mode frequency is an important parameter in the multiphonon absorption model [30], since it designates the maximum phonon frequency.

Characterization of the fundamental optical modes of yttria doped with 9 mole-percent lanthana [7, 8] shows similar lattice vibrational structures that are broader and red-shifted to lower frequency by 5–12 wave numbers. The multiphonon absorption edge is also red-shifted by a similar amount [30].

At frequencies below the last fundamental optical mode, absorption decreases and the material becomes transparent. The magnitude of absorption is thought to be a combination of contributions from both the tail of the fundamental lattice vibrations and various multiphonon difference bands. The index of refraction now also includes the effect of lattice vibrations. Estimates of low-frequency absorption made from the red wing of the fundamental modes (Table I) are about 40% of the imaginary index-of-refraction values determined by Stead and Simonis [36] in the 4–16 cm^{-1} region. Smith and Loewenstein [37] measured the absorption coefficient of Yttralox (yttria with 10 mole-percent thoria) in the 50–200 cm^{-1} region and found absorption similar to pure yttria.

The low-frequency index of refraction of yttria was measured by Stead and Simonis [36] at 3.43 (dielectric constant of 11.76), which agrees well with the measurements of Hyde [38] when corrected to full density and room temperature. The same value was obtained for Yttralox by Smith and Loewenstein [37], and a higher value of 3.49 (dielectric constant of 12.2) is given by Wei *et al.* [29] for yttria with 9 mole-percent lanthana. Westphal and Sils [39] report a room-temperature dielectric constant of 11.3 for 97% dense, 99.8% pure yttria.

Temperature dependence of the low-frequency index of refraction was measured by Hyde [38], who also found a resonance at very low frequencies (below 10^5 Hz). His dn/dT value of 1.05×10^{-4}/K ($d\varepsilon/dT = 7.2 \times 10^{-4}$/K) agrees well with the value predicted from the fundamental lattice-vibration model [35]. This model underpredicts the low-frequency index by 1.5%, probably because several weak vibrational modes have not been modelled (only 11 of the 16 modes predicted by group theory are observed and modeled).

Low-frequency dielectric constant data reported by Hyde [38] and Westphal and Sils [39] show a free-carrier effect that grows rapidly with temperature. Conductivity measurements by Tallan and Vest [27] also

indicate a growth in free carriers with temperature.

Table II was constructed from measurements reported in the literature as well as model predictions [30, 35]. Real-index (n) data from 2–40 eV, and imaginary-index (k) data from 5.2–40 eV are taken from the measurements of Tomiki *et al.* [16]. Real-index data below 6 eV (0.21–12 μm) are calculated from the Sellmeier dispersion relationship (Eq. 2) of Nigara [17]. Measurements of k (determined from absorption coefficients) reported by DeShazer *et al.* [18] are also shown. These data may include significant extrinsic absorption because the values are much higher than those in Tomiki *et al.* [16].

Lattice-vibration-model results [35], using Nigara's [17] representation of the electronic contribution to index, are used to calculate the index of refraction for wavelengths of 1 μm and longer. Laser-calorimetry results for k at 2.9 and 3.9 μm by Detrio and Greason [40] are also given to represent typical extrinsic absorption in the transparent region. Multiphonon absorption becomes important (greater than extrinsic absorption) at wavelengths beyond 4.5 μm. Values in the table up to 10 μm are calculated using the methods of Thomas *et al.* [30], which are validated by measurements. Beyond 10 μm, the fundamental (one-phonon) contributions become dominant. In this region, n and k are calculated using the parameters in Table I as described by Thomas [35]. The results are validated by comparing calculated reflection spectra to measurements.

Measurements of Stead and Simonis [36] and Hyde [38] best represent the low-frequency characteristics of yttria. In this region, one-phonon-model predictions [35] of k are only 40% of measurements [36], and real-index values are 1.5% low compared to measurements [36, 38].

The accuracy of available index data is unknown. In all data, the uncertainty in the values is probably in the least significant digit reported in Table II. In spectral regions where several sources of data exist, there is a large disparity between references.

Figure 1 shows a composite of the complex index of refraction based on the data of Table II.

Table III gives temperature dependence for the real part of the index of refraction. Measurements of dn/dT by Wei *et al.* [29] give 5.0×10^{-5}/K and 3.2×10^{-5}/K at wavelengths of 0.357 and 3.39 μm, respectively. Measurements made by A.P.L./J.H.U. at 0.633 μm give much lower values: 8.4×10^{-6} for pure yttria and 8.4×10^{-6} for lanthana-doped yttria. The temperature change in index of refraction at microwave frequencies remains nearly linear for most oxides up to 1000 K. This characteristic is likely to be true for yttria also, but has not been experimentally verified.

Temperature-dependent absorption predictions from optical models of yttria [30, 35] have been used to estimate total hemispherical emissivity of pure, transparent yttria over the 200 to 1000 K temperature range, where the models are expected to give the best results and intrinsic (temperature-

produced) defect absorption is believed to be insignificant [9]. These results were obtained by estimating the complex refractive index at a given temperature, calculating directional emittance for a specific slab thickness, integrating over angle, and convolving the resulting spectral hemispherical emittances with the Planck function.

Table IV gives the resulting total hemispherical emittance for semi-infinite slabs as a function of slab thickness. Since total hemispherical emissivity is an important function for radiation-relief calculations and is needed to correct property measurements such as thermal conductivity, we have included this calculated result.

NOTES ADDED IN PROOF

A recent theoretical study of yttria electronic structure and bonding is given in [41]. Results agreed well with experiments.

A recent measurement of the index of refraction of 9% lanthana-doped yttria made by the minimum deviation method gave a value of 1.9294 ± 0.0001 at 546 nm [42]. This value, believed to be accurate, is considerably below the value given in [24], and much closer to the index of pure yttria. Other measurements between 0.4 and 2.3 μm show the same trend [42].

Details of the measurement of dn/dT at 0.6368 μm in Table III are given in [43]. Spectral and directional scatter measurements of commercial ALON are given in [44].

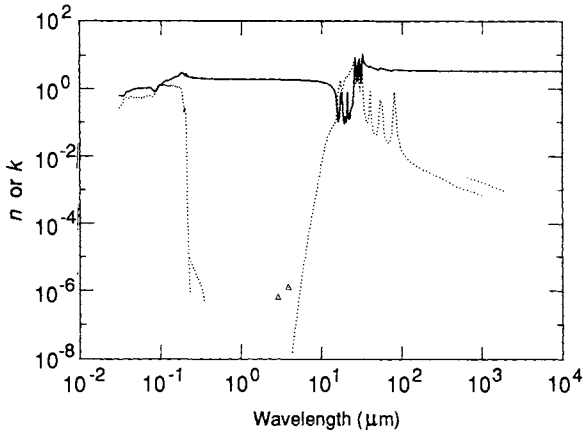

Fig. 1. Log–log plot of n (solid line) and k (dashed line) versus wavelength in micrometers for yttrium oxide. Data from various sources sometimes do not join together in overlap regions. Symbols are laser calorimetry measurements of k.

TABLE I

Fundamental Infrared Lattice-Vibration Parameters for Yttrium Oxide[a]

Mode	Transverse optical frequency (cm^{-1})	Strength	Normalized width	Longitudinal optical frequency (cm^{-1})	Refs.
1	120	0.20	0.035	121	[34,35]
2	172	0.10	0.025	173	[34,35]
3	182	0.15	0.025	183	[34,35]
4	241	0.20	0.025	242	[35]
5	303	2.60	0.0135	315	[35]
6	335	1.75	0.0115	359	[35]
7	371	2.65	0.021	412	[35]
8	415	0.04	0.011	456	[35]
9	461	0.05	0.015	486	[35]
10	490	0.005	0.018	535	[35]
11	555	0.095	0.025	620	[35]
		Total = 7.86			

[a]The transverse optical frequency (ν_j) is the location of the mode. The strength ($\Delta\epsilon_j$) is the contribution of the mode to the dielectric constant. The normalized width (γ_j) is the mode width divided by the mode frequency. The complex dielectric constant (ϵ) is then modeled as a function of frequency (ν) by

$$\epsilon(\nu) = \epsilon_\infty + \sum_j \frac{\Delta\epsilon_j \nu_j^2}{\nu_j^2 - \nu^2 + i\gamma_j \nu_j \nu} ,$$

where the ϵ_∞ term (= 3.579) represents the electronic contributions to the dielectric constant (plus one). Nigara *et al.* [32] also observed modes 5-11. Bloor and Dean [33] observed a mode at 197 cm^{-1} in measurements made at 1.5 K. Such a mode was not observed by McDevitt and Davidson [34].

Preface xvii

Part I DETERMINATION OF OPTICAL CONSTANTS

Chapter 1 **Introductory Remarks** 3
EDWARD D. PALIK

I. Introduction 3
II. The Chapters 4
III. The Critiques 5
IV. The Tables 5
V. The Figures of the Tables 5
VI. Corrections, Additions, and Comments 6
References 12

Chapter 2 **Determination of the Far-Infrared Optical Constants of Solids by Dispersive Fourier Transform Spectroscopy** 13
T. J. PARKER, K. A. MASLIN, and G. MIRJALILI

I. Introduction 13
II. The Materials 20
Acknowledgment 55
References 55

Chapter 3 **Photothermal/Photoacoustic Spectroscopic Measurements of Optical Absorption Coefficients in Semiconductors** 59
ANDREAS MANDELIS

I. Introduction 59
II. Photoacoustic Spectroscopy (PAS) 60

Preface

The *Handbook of Optical Constants of Solids* has now grown to three volumes. The publication of *HOC I* in 1985 and *HOC II* in 1991 has reduced but not exhausted the available materials of scientific and technological interest. One can ask what materials are left to critique. There are several candidates.

There is a trickle of recently published papers remeasuring "old" materials already critiqued in *HOC I* and *HOC II.* This is the case for Si, Al_2O_3, Si_xGe_{1-x}, which are revisited in *HOC III.* This will be worthwhile to do for several other materials from time to time.

We have not developed the courage to attack the III–V ternary and quaternary materials in detail except for $Al_xGa_{1-x}As$ *(HOC II),* so important in laser and electronic applications. We looked at the II–VI ternary compound $Hg_{1-x}Cd_xTe$ *(HOC II),* important in infrared-detector applications, as well as the IV-VI compound $Pb_{1-x}Sn_xTe$ *(HOC II).*

Our dream of critiquing all the alkali halides from LiF to CsBr is not yet fulfilled.

We have noticed a lack of data for the index of refraction n but not for the extinction coefficient k for gemstones. The gemologist only seems interested in n at the Na D line. We noticed from a scan of several gem books that n is not given throughout the visible. For most purposes, n is considered a constant. But to the physicist, n is not a constant. Since gemstones must be "full of impurities" to give them their wide variety of colors, the gemologist does measure the visible absorption spectrum to determine the impurity absorption bands. The physicist usually prefers pure crystals (at least insulators). We have previously critiqued diamond, sapphire, quartz, and spinel in pure form, the latter three being the starting point for several gemstones including ruby, amethyst, agate, opal, and chrysoberyl. In *HOC III* we add yttrium aluminum garnet and zircon. There are no n measurements in the visible except at 589.0 nm for zircon. We need to find more technology uses for gemstones which, in turn, will spur measurements of n and k! We could not find a critiquer for cubic zirconia, which to us is quite different from diamond in optical properties, but serves as "fake" diamond for many people.

As with *HOC I* and *HOC II,* I am indebted to the many scientists for their work in *HOC III,* writing chapters on still more ways to measure optical constants and writing critiques tabulating the optical constants of more than 60 additional materials.

INTRODUCTION I

The two previous volumes of *Handbook of Optical Constants of Solids (HOC I* and *HOC II)* contained about 85 materials. The present volume adds about 58 more materials, roughly divided into equal numbers of metals, semiconductors, and insulators. A long list of potential materials was circulated among possible critiquers. They chose and/or recommended the ones presented here. There are still some materials omitted because of a lack of critiquers. These include Bi, B, Ba, Ca, Cd, Pb, Zn, Zr, ZnO, HgS, HgSe, $Pb_xSn_{1-x}Se$, PbO, MoS_2, Cd_3As_2, GaS, LiOH, NaBr, NaI, KF, LiCl, LiBr, ZrO_2, BaO, and NiO. Note that 43 of the 92 chemical elements are done and 143 of the 100,000 (or more) chemical compounds. We have omitted glasses generally, which are covered to some extent by Efimov [1] and Tropf *et al.* [2].

There is some loose use of the words *semiconductor* and *insulator* in *HOC I* and *HOC II* based primarily on the band gap being less or greater than

3 eV. AgCl, AgBr, AgI, BSO, and BGO are considered as semiconductors because their electrical properties can be controlled by doping during growth of the crystals, but they may end up in either category. Diamond is invariably thought of as an insulator, although natural diamonds can be found with semiconducting properties.

II THE CHAPTERS

The chapters are meant to describe experimental techniques for measuring n and k.

In Chapter 2, Parker *et al.* discuss the determination of n and k by differential Fourier transform spectroscopy in the far infrared. This is an elegant way to obtain n and k from the reflection amplitude and phase and has been applied to many semiconductors and insulators. It is of interest to compare these newer optical constants with those in *HOC I* or *HOC II,* which have generally been obtained by Kramers-Kronig (K-K) analysis or classical oscillator fit.

In Chapter 3, Mandelis describes the use of photoacoustic spectroscopy to determine k. While this chapter stresses semiconductors, several variations of the technique have also found widespread use for other materials.

In Chapter 4, Briggs discusses photothermal deflection as a method of determining k. It is done with two intense beams, one to heat up a small spot on a sample and a second to detect bending of the sample as it expands locally.

In Chapter 5, Boukari and Lagakos describe the determination of n and k by Brillouin scattering. While not usually thought of as a technique for determining optical constants, there are novel ways to determine n an k in highly absorbing materials and n in transparent slabs and thin films.

In Chapter 6, Auslender and Hava develop models for calculating n and k in n-Si for the infrared region for free-electron concentrations from 10^{16} to 10^{20} cm^{-3}.

In Chapter 7, Palik collects a number of optical parameters for all the materials in *HOC I, HOC II,* and *HOC III* including crystal structure, space group symmetry, unit cell dimensions, number of molecules/unit cell, optic and acoustic irreducible representation, transverse and longitudinal lattice vibration frequencies, plasma frequency, band gap, and d.c. dielectric constant.

There were suggestions for chapters on the loss-tangent method at low frequencies and on the prism minimum-deviation technique (still the best way to determine n), but these could not be done at this time.

THE CRITIQUES III

The critiques are meant to be the critiquer's own judgment of the best room-temperature values of n and k over the widest spectral range. As the volumes have progressed, we have expanded the range a little with a few critiques including above and below room-temperature data. Sometimes there are two overlapping sets of data from two different laboratories which can be compared. This sometimes happens in the far infrared where reflectivity is K-K analyzed and/or a classical oscillator model is applied. Generally, it is not a good idea to give the reader a choice of data—it is the job of the critiquer to make the choice. Sometimes, however, a comparison sheds light on the problems arising in the measurement of optical constants such as wavelength calibration and determination of absolute reflectivity. Recently, spectroscopic ellipsometry has grown into a wide-spread technique for the 1.5–6 eV region, probably supplanting K-K analysis of reflectivity.

We have returned to a few materials done in previous volumes because more data have become available. Therefore, we revisit Al_2O_3, Si_xGe_{1-x} and Si.

THE TABLES IV

The tables of n and k have become more individual to meet the needs of the individual critiquers. We maintain the columns labeled eV, cm^{-1}, μm, n, k and proceed down the column in decreasing eV. Reference brackets [1] start at the top of a given data column and are understood down the column until a new data set occurs, which is then labeled [2], for example. We promoted exponential notation especially of k, ideally for every column, but have not yet reached that stage of uniformity.

To facilitate editing the tables for the Optical Society of America, we have requested that the exponential notation be used at every row, rather than omitting the exponent until it changes value somewhere down the column.

THE FIGURES OF THE TABLES V

The critiquers have taken more leeway with the figures, since they had to produce them with whatever graphics software they had available. In previous editions, all the figures were prepared by the same artist who kept the style uniform. Now critiquers can use data points (usually ○○○ for n and △△△ for k). Data points can be connected with lines, or just lines can be used (usually —— for n and --- for k). In the past, both n and k were plotted on the same

figure with the same log-log scale. Since the extent of k determined the number of decades of the log scale for the ordinate, ($10^{-7} < k < 10^{1}$), n was squeezed. Also, for solids with a lot of vibration bands, this region got very busy. Now some critiquers have separated n and k plots to show the structure more clearly.

The drawbacks in having each critiquer make his own figure are the many problems of font size, tick-mark position, and border thickness, remembering that the figure will be reduced in published form.

VI CORRECTIONS, ADDITIONS, AND COMMENTS

A Optical Constants of CdS

A correction and addition to the data for CdS from *HOC II* needs to be made according to the critiquer, L. Ward. Data of Dutton[1] near the band edge has been added. The extinction coefficient for both $\mathbf{E}_{\|c}$ and $\mathbf{E}_{\perp c}$ has been determined by transmission measurements of thin slabs of different thicknesses. These can be compared to data of Cardona and Harbeke[2] for bulk-oriented samples obtained from K-K analysis of reflectivity with polarized light. Data of Khawaja and Tomlin[3] for films deposited on quartz substrates (assumed to be polycrystalline) were obtained from transmittance and reflectance measurements; these data have been reassessed to correct an error in reading the wavelength scale. The results are presented in Table I. While above the band gap the results for k are comparable, below the band gap where absorption decreases orders of magnitude, the results differ drastically among the three data sets. We suspect that K-K analysis of reflectivity in Cardona and Harbeke gives poor results for $k \ll 1$ compared to transmittance of slabs in Dutton. For the polycrystalline films in Khawaja and Tomlin, it is not obvious why k is so much larger compared to the data of Dutton below the band gap. Perhaps there was significant light scattering from defected material, which was mistaken for absorption.

B Optical Constants of Metal Films

The optical constants of metals in *HOC I, II,* and *III* can be compared with those given in Optimatr, a computer program to calculate optical prop-

erties of materials. This software is available from ARSoftware, 8201 Corporate Dr., Suite 1110, Landover, MD 20785. It is copyrighted by the Johns Hopkins University/Applied Physics Laboratory and ARSoftware, Inc. The calculational procedures, based on several literature models for determining optical properties of solids, are based on the works of M. E. Thomas and W. J. Tropf. The data for metals in Optimatr were essentially that of Ordal *et al.*, who fitted a Drude model to many sets of existing data. In comparing the optical constants of metals from Optimatr and *HOC* in the visible and near-infrared regions, one finds for Au and Ag especially, significant variations in n and k (up to a factor of two). This is due to the fact that data from different laboratories were used. Where the data from the same laboratories were used, the agreement is much better, of course.

This general problem of the variation of optical constants of metal films deposited at different laboratories and with different deposition techniques, has been discussed by Aspnes *et al.* with regard to gold. They find that voids

and grain size in the films can account for significant variations in n and k, as demonstrated by their spectroscopic-ellipsometry measurements in the 1.5–6 eV spectral region. Therefore, it would appear that metal films (and especially Au and Ag) should be measured directly if the optical constants are needed for an application. Also, it would be good to measure the optical constants of single crystals of the metal, if polishing the surface can be accomplished with minimal damage. Since k is so large (generally > 1), the optical skin depth is typically less than a few hundred Angstroms. Native oxides can also pose a problem.

We list a number of papers about Au which trace this problem and may be of interest to the reader.

C Henke Model for the Elements

The most recent update for the scattering factors of the chemical elements has appeared in B. L. Henke, E. M. Gullikson and J. C. Davis, X-Ray interactions: Photoabsorption, scattering, transmission, and reflection at E = 50–30000 eV, Z = 1–92. *At. Data Nucl. Data Tables* **54,** 181 (1993).

These data are also available by computer. In fact, the calculation of n and k can be carried out at

http://www-cxro.lbl.gov/optical_constants

Extension to compounds is also possible, although the values will not be correct at energies near bonding energies. Deep-lying K and L absorption edges are well approximated, however.

More-Recent Papers about Optical Constants D

Since 1985 for the materials in *HOC I,* and since 1991 for the materials in *HOC II,* more papers have appeared discussing optical constants. We list those papers below which we have noticed.

Occasionally, an older paper of interest, missed or omitted by the critiquer, has been included (without comment).

E Optical Constants on Disk

The tables of *n* and *k* from *HOC I* and *HOC II* have been edited and put on disk by the Optical Society of America. One 3.5″ disk in MS DOS version in compressed format is available from Electronic Products, Optical Society of America, 2010 Massachusetts Ave., N.W., Washington, D.C. 20036. Hopefully, this can be expanded to include the materials in *HOC III* shortly.

I INTRODUCTION

We present values of the far-infrared optical constants of a selection of alkali halide crystals (NaCl, KCl, KBr, KI, and RbCl), II–VI semiconductors (CdTe, ZnSe) and III–V semiconductors (GaP, GaAs, GaSb, InP, InAs, and InSb) determined by dispersive Fourier transform spectroscopy (DFTS). DFTS is a technique for determining the optical constants of materials in the solid, liquid, or gas phase from direct measurements of the amplitude and phase reflection or transmission coefficients of suitable samples as a function of frequency, $f = c/\lambda$, or wavenumber, $\nu = 1/\lambda$, where c is the speed of light in vacuo and λ is the wavelength. The technique was pio-

neered in the early 1960s by Chamberlain and colleagues [1–3] at the National Physical Laboratory in the United Kingdom, and by Bell and colleagues [4–6] at the Ohio State University in the United States. A number of extensive reviews of the applications of DFTS in solid, liquid, and gas state spectroscopy have been written over the past twenty years [7–10]; we shall not repeat that material here, but shall very briefly summarize the principles of the technique and then concentrate on aspects of the method which have a direct bearing on the accuracy of the determination of the optical constants.

In DFTS, a suitable sample, usually prepared with plane-parallel surfaces, is placed in one arm, usually the fixed arm, of a two-beam Michelson interferometer for measurements either in reflection or transmission; three geometrical arrangements have been described in the literature [8], and these are illustrated schematically in Fig. 1. Two interferograms are usually recorded, a sample interferogram $I_S(x)$, measured as a function of optical path difference, x, with the sample in place in the interferometer, and a reference, or background interferogram, $I_B(x)$, recorded after replacing the sample with a suitable reference material: in reflection DFTS, the reference material would be a reference mirror placed in the plane previously occupied by the sample; in transmission DFTS, the reference material would be the slab of vacuum left in the instrument after removing the sample. In either case, the information containing the frequency dependence of the amplitude and phase reflection or transmission coefficients is obtained by computing the ratio

$$L(\nu) = L_0(\nu)\exp i\phi_L(\nu) = \frac{FT[I_S(x)]}{FT[I_B(x)]} \tag{1}$$

of the complex Fourier transforms, $FT[I_S(x)]$ and $FT[I_B(x)]$, of the two recorded interferograms. The exact form of the relationship between $L(\nu)$, commonly known as the complex insertion loss, and the optical constants, (n, k), is determined by the details of the experimental arrangement.

In this article we shall review the optical constants of a selection of simple binary solids calculated from amplitude and phase reflection coefficients determined by reflection DFTS. In this geometry (Fig 1(c)), as already pointed out, the background interferogram is recorded after replacing the sample by a reference mirror. This is the simplest geometry encountered in DFTS, and the complex insertion loss is equal to the ratio of the complex amplitude reflection coefficients of the sample and the reference mirror. Thus, for reflection DFTS, or amplitude reflection spectroscopy as it is frequently known, the complex insertion loss is given by

$$L_0(\nu)\exp i\phi_L(\nu) = \frac{r_s(\nu)\exp i\phi_s(\nu)}{r_m(\nu)\exp i\phi_m(\nu)} \tag{2}$$

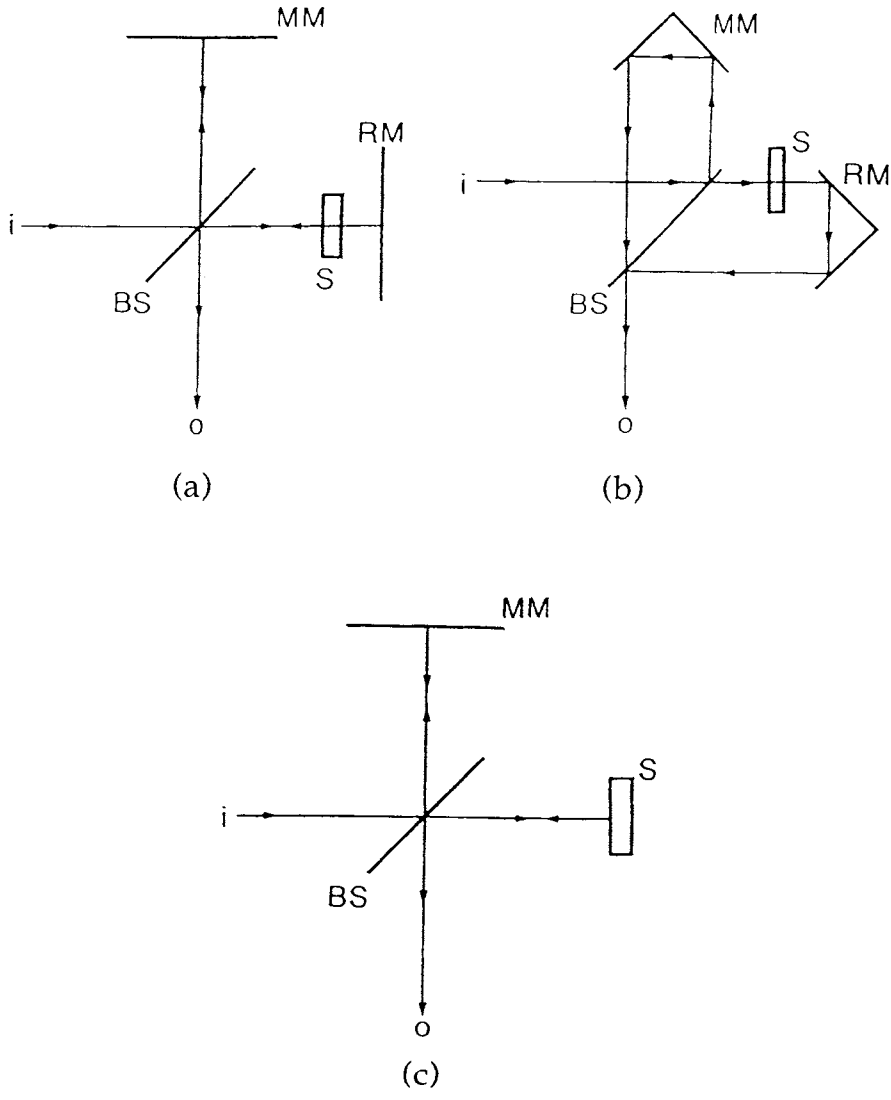

Fig. 1. Schematic drawing of the three experimental arrangements used in DFTS. (a) Double-pass transmission DFTS, (b) Single-pass transmission DFTS, and (c) Reflection DFTS, or amplitude-reflection spectroscopy. Key: *i*, input beam; *o*, output beam; *MM*, moving mirror; *RM*, reference mirror; *BS*, beam splitter; *S*, sample.

In DFTS in the far infrared, it is common practice to regard the reference mirror as a perfect mirror with a complex-amplitude reflection coefficient

$$r_m(\nu) \exp i\phi_m(\nu) = \exp i\pi. \tag{3}$$

Consequently, the amplitude and phase reflection coefficients of the sample are determined in a straightforward way from the measured interferograms, as

$$r_s(\nu) = L_0(\nu), \qquad \text{and} \qquad \phi_s(\nu) = \phi_L(\nu) + \pi. \tag{4}$$

In reflection DFTS, measurements are usually made at or at very nearly normal incidence, and samples are chosen with sufficient thickness to suppress all but the primary reflected partial wave from the front surface of the sample. Under these conditions, the simplest form of Fresnel's equations can be used, and the optical constants and amplitude and phase reflection coefficients are related by

$$n(\nu) + ik(\nu) = \frac{1 + r_s(\nu)\exp i\phi_s(\nu)}{1 - r_s(\nu)\exp i\phi_s(\nu)} \tag{5}$$

The intensity reflection coefficient, or reflectivity, $R_s(\nu)$, is related to the amplitude reflection coefficient by

$$R_s(\nu) = \boldsymbol{r}_s(\nu)\, \boldsymbol{r}_s{}^*(\nu), \qquad \text{where} \qquad \boldsymbol{r}_s(\nu) = r_s(\nu) \exp i\phi_s(\nu) \tag{6}$$

is the complex amplitude reflection coefficent, and $\boldsymbol{r}_s{}^*(\nu)$ is its complex conjugate.

DFTS has the advantage that both the amplitude and the phase are measured directly at all frequencies in the measured range; this eliminates uncertainties in $\phi_s(\nu)$ which arise due to truncation of the measured spectrum when the phase is calculated from the measured reflectivity using the Kramers-Kronig dispersion relations. As already mentioned, DFTS is invariably used at normal, or near-normal incidence, so that the simplest forms of the Fresnel equations can be used. Frequently a combination of reflection and transmission DFTS can be used very effectively to determine n and k at most frequencies. When R_s is small, as can be seen from Eq. (6), measuring r is an advantage; Johnson and Bell [11] have shown that values of R_s as small as 4×10^{-4} can be measured reliably by reflection DFTS. However, when R_s is large, this is a disadvantage because r_s for the sample then differs from the value for the reference mirror by even less than R_s. Finally, reflection DFTS cannot be used to determine reliable values of $k(\nu)$ in spectral regions where the sample is transparent, because the phase is then very small, as discussed further below.

In reflection DFTS, applicable here, it is convenient to consider uncertainties in the measured amplitude and phase reflection coefficients separately. Uncertainties in the amplitude arise in the same way as they do in

other forms of spectroscopy in which, usually, in reflection spectroscopy, it is the intensity, R_s, of the reflection coefficient which is measured. Provided that adequate precautions have been taken to eliminate systematic errors, uncertainties in r_s or R_s arise primarily from random uncertainties in the detector response. However, when using metal reference mirrors which are usually fabricated by metallizing optically flat glass blanks, systematic errors also arise due to lack of perfect reflection of the metal surface. This latter point has been discussed by Eldridge and Staal [12] and Staal and Eldridge [13] and corrections to both the amplitude and the phase reflection coefficient associated with such mirrors were taken into account in their determinations of the optical constants of NaCl by reflection DFTS. Comparisons of published data for NaCl, KCl, and KBr presented in this article indicate that such corrections are necessary if the technique is to be used to full advantage. Birch [14] has shown how, by using a thick transparent slab of a material such as silicon as a reference reflector, a combination of reflection and transmission DFTS can be used to determine absolute values of the amplitude and phase reflection coefficients of thin metal mirrors in the far infrared.

In the case of the phase reflection coefficient, a number of additional systematic errors can arise which are associated mainly with the way in which the comparatively small wavelengths encountered in the far infrared ($\lambda \sim 20$–500 μm) translate into a need for very precise technology for sampling the interferograms and handling optical components (such as the sample and reference mirror surfaces). In most reflection DFTS experiments, the sample and reference mirror surfaces must be precisely interchanged during the experiment. Let us first consider the possible sources of systematic phase error which are encountered in a far-infrared interferometer equipped with a mechanical step-drive mechanism for scanning the moving mirror. It will be convenient to begin by taking as the goal for our phase measurements a systematic error which is equal to the random phase error equivalent to the random error in the amplitude reflection coefficient. A convenient yardstick is a signal-to-noise ratio of 100, leading directly to an uncertainty in the amplitude reflection coefficient of $\delta r_s = 0.01$, or 1%. The equivalent uncertainty in the phase is $\delta\phi_s = 0.01 \times \pi$ radian, or $\delta\phi_s \sim 0.5°$. The most serious systematic phase errors are as follows.

1. Potentially most serious of all is the phase error resulting from failure to place the reference-mirror surface precisely in the same plane as the sample reflecting surface. If we consider measurements at 100 cm^{-1}, for instance, then a phase uncertainty of 0.5° would occur if the error in the positioning of the two optical components were $\delta x = (\lambda/2 \times 360)\,\delta\phi_s \sim 0.1$ μm. This is a very severe constraint indeed, bearing in mind that the limiting precision of most mechanical engineering work lies in the range between 2.5 and 25 μm.

2. Mechanical step drives for interferometers and, in particular, backlash errors which occur when such drives are operated over a sequence of scans, as required when recording background and sample interferograms in turn, can often introduce uncertainties in the position of the moving mirror of a magnitude $\delta x \sim 0.1$ μm.
3. Differential thermal expansion in the two arms of the interferometer can be the cause of significant systematic phase errors. If the optical components are at a distance L from the beam divider, then a relative change in the temperature of the two arms of the interferometer of δT will result in a differential change in the lengths of the two arms of the interferometer of $\delta L = \alpha L \delta T$, where α is the coefficient of thermal expansion of the material from which the interferometer is constructed. If we take $L = 30$ cm, and $\alpha = 2 \times 10^{-5}$ K^{-1}, corresponding to Al, then we must have $\delta T < 0.015$ K, if $\delta L < 0.1$ μm. Temperature control with this level of precision is fairly easily achievable, but the figure for δT does indicate that this aspect of instrument design cannot be ignored.
4. The flatness of the sample and reference mirror surfaces should also satisfy the criterion calculated in (1) above, i.e., the surface flatness should be within ~ 0.1 μm at all points across the surface. Apart from placing severe requirements on the quality of the flatness and the optical polish of these optical components, the two components must also be cut from material which is sufficiently thick to maintain the quality of the surface for the duration of the measurements. Usually, this means that for optical components of $\sim$ 10 mm in diameter, the thickness should not be less than $\sim$ 6 mm.

Fortunately, there are ways of avoiding most of these phase errors. Parker *et al.* [15] have described how the need for the accurate replacement of reflecting surfaces can be avoided by metallizing part of the sample surface for use as a reference mirror, and this technique has been used by a number of authors, including Pai *et al.* [16], Eldridge and Staal [12], Staal and Eldridge [13], and Plumb and Birch [17]. Maslin and Parker [18] have shown that by designing an interferometer with a subsidiary He-Ne laser beam running along the optical axis of the far-infrared beam and using laser fringe-counting techniques, the second and third of the systematic phase errors listed above can also be avoided. It has been shown by Wan Abdullah and Parker [19] that this method also significantly reduces noise in the measured spectrum arising from random errors in sampling the interferogram; such errors are often present when a mechanical step drive is used for the moving mirror. Burton and Parker [20, 21] have demonstrated that systematic phase errors arising from non-flatness of the sample surface can be reduced to the order of one degree when $\lambda > 0.4$ μm (i.e., for DFTS at all wavelengths exceeding those in the UV) by suitably coating the sample surface and reusing it as the reference surface; the method requires the use of four interferograms and has been demon-

strated with reflection DFTS measurements in the visible region of the spectrum, but it has not yet been used in the far-infrared. Birch [22, 23] has investigated these so-called pseudocoherence effects associated with nonflatness of optical components theoretically.

By far the greatest single difficulty in reflection DFTS is the need for the accurate mechanical replacement of the reference mirror and sample reflecting surfaces. However, careful consideration of the form of the Fresnel equations for reflection readily demonstrates that this difficult operation can often be avoided. In many materials of interest, and that applies to those considered in this article, there are frequency ranges in the measured range in which the extinction coefficient is very small compared with the real refractive index, i.e., $k(\nu) \ll n(\nu)$. In the limit of small k, it follows from Eq. (5) that n and k are given by

$$n(\nu) \sim \frac{1 + r_s(\nu)}{1 - r_s(\nu)} \text{ and } k(\nu) \sim \frac{2r_s(\nu)\phi_s(\nu)}{[1 - r_s(\nu)]^2}. \tag{7}$$

The smallest measurable value of $\phi_s(\nu)$, corresponding to the noise limit if the signal-to-noise ratio is 100, is 0.01 radian. For the semiconductors studied by Maslin *et al.* [24], $r_s(\nu) \sim 0.5$ well above the reststrahl region where $\phi_s(\nu)$ is small. From Eq. (7), the corresponding lower limit for the value of k which can be measured by reflection DFTS is then $k \sim 0.04$, and the associated experimental uncertainty would be $\sim$100%. In regions where k is much smaller and the sample is transparent, it follows from Eq. (7) that for practical purposes, $\phi_s(\nu)$ approaches zero. In the alkali-halide crystals where ϵ_∞ is smaller, smaller values of k are accessible to reflection DFTS, but the accuracy of the determination of k is still severely limited by the difficulty of measuring $\phi_s(\nu)$. At a suitable reference frequency, ν_H, sufficiently far above the reststrahl band of a binary solid, we can set $\phi_s(\nu_H) = 0$ on physical grounds. $\phi_s(\nu) = 0$ also at $\nu = 0$. It follows that we can dispense with the experimental requirement to mechanically locate the reference mirror and sample surfaces in precisely the same plane. Instead, a much simpler experimental requirement of placing them in precisely parallel planes will suffice; planes separated by $\delta x \sim$ a few microns are easily achievable experimentally and this will not introduce systematic errors in $r_s(\nu)$, even if the radiation is poorly collimated. Then, after recording the two interferograms and computing the sample phase reflection coefficient, $\phi_s(\nu)$, using Eq. (4), the value of $\delta x = \phi_s(\nu_H)/4\pi\nu$ required to correct the measured phase $\phi_s(\nu_H)$ at ν_H can be calculated and a linear phase correction

$$\delta\phi_s(\nu) = 4\pi\nu\ \delta x \tag{8}$$

applied throughout the phase spectrum. This procedure was followed by Maslin *et al.* [24] when they used reflection DFTS to determine the optical constants of the II–VI and III–V semiconductors presented here. The origi-

nal numerical data were lost when the group moved their laboratory from London to Colchester in 1991; computer-generated graphs of the numerical data for all samples were presented on paper 25 × 20 cm^2 in area in the Ph.D. thesis by Maslin [25], and the data for semiconductors presented here has been obtained by carrying out digital scans of those graphs. We consider that the errors introduced by this process have not significantly added to the spectroscopic errors of the original data.

A detailed statistical analysis of experimental uncertainties in reflection DFTS was carried out by Pai *et al.* [16]. They used a method in which part of the sample surface was metallized [15] and used to provide the reference phase measurement, thus obviating the need for the precise mechanical replacement of reflecting surfaces. They listed values of n and k, and of the associated experimental uncertainties Δn and Δk, throughout the reststrahl bands of eight alkali halide crystals: NaF, NaCl, KCl, KBr, KI, RbCl, RbBr, and RbI at 100 and 300 K. We reproduce their estimates of Δn and Δk in Tables I–V for five alkali-crystals here: NaCl, KCl, KBr, KI, and RbCl. Because of the similarity between the far-infrared optical properties of the alkali halides and the II–VI and III–V semiconductors, these experimental uncertainties provide a useful guide to the frequency dependence of the experimental uncertainties for the II–VI and III–V semiconductors listed here.

II THE MATERIALS

A Alkali Halides

1 *NaCl*

The far-infrared optical constants of NaCl determined by Pai *et al.* [16] at 300 K at a resolution of 2 cm^{-1} using DFTS are shown in Fig. 2 and listed in Table I, where they are compared with values measured by reflection DFTS by Eldridge and Staal [12], and listed numerically by Eldridge and Palik [26]. Pai *et al.* [16] also published numerical values for n and k for NaCl at 100 K. The two sets of values listed in Table I are generally in reasonable agreement, within the limits of the experimental errors listed by Pai *et al.*, differing at most by a few percent except in the region of high reflectivity where n and k have their highest values. Eldridge and Staal used aluminium as a reference surface and corrected for the fact that aluminium is not a perfect reflector and does not have a phase reflectivity of exactly π: this could account for the difference between the two sets of data in Table I where n and k are large. This is supported by the data presented below for

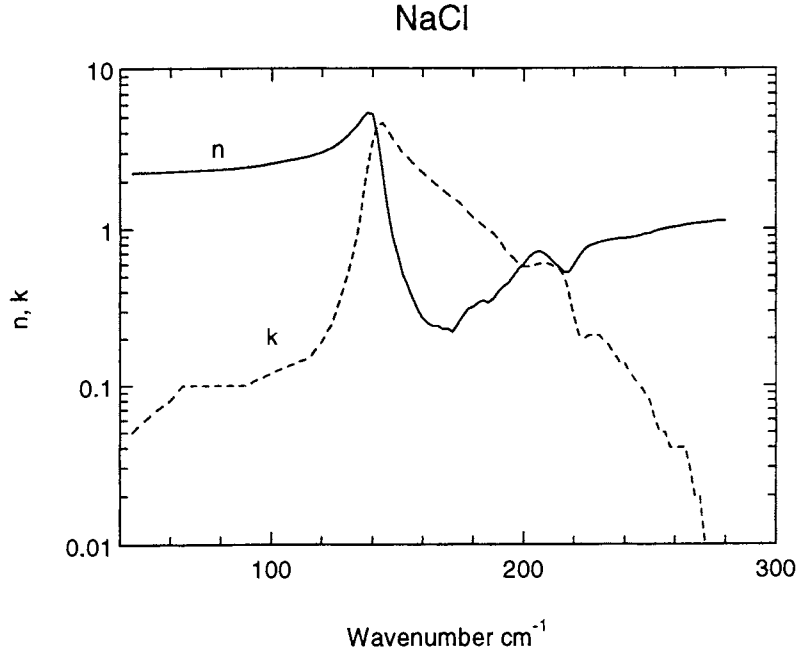

Fig. 2. Log-linear plot of the far-infrared optical constants, *n* and *k*, versus wavenumber for NaCl at 300 K. (From Pai *et al.* [16] with permission from the publisher.)

KCl and KBr; we can conclude that the corrections to the reference-mirror reflectivity carried out by Eldridge and Staal are worthwhile and to be recommended. Below 110 cm^{-1} and above 340 cm^{-1} where the phase reflection coefficient is very small, Eldridge and Staal [12] obtained the phase indirectly from transmission measurements on cleaved crystals, which yielded directly the absorption coefficient.

KCl 2

The far-infrared optical constants of KCl determined by Pai *et al.* [16] at 300 K at a resolution of 2 cm^{-1} using DFTS are shown in Fig. 3 and listed in Table II. They also published numerical values for n and k for KCl at 100 K. Johnson and Bell [11] also determined the optical constants of KCl at 300 K by reflection DFTS at 2 cm^{-1} resolution, and Palik [27] obtained numerical values by reading their graphs: a selection of these values is given in Table II, and it can be seen that there is very good agreement between the two sets of data, somewhat better than the agreement reported above between the data of Pai *et al.* [16] and Eldridge and Staal [12] for NaCl. Nei-

280	1.13	0.01	0.01	1.10	2.3 E-2

ther set of data for KCl was corrected for the reference-mirror reflectivity; this supports the view that differences in the data of Pai *et al.* [16] and Eldridge and Staal [12] for NaCl can be attributed to the corrections which Eldridge and Staal made for the reflectivity of their Al reference mirror. Thus, for measurements with this accuracy, corrections for the imperfect reflectivity of metallized reference mirrors are to be recommended.

KBr 3

The far-infrared optical constants of KBr determined by Pai *et al.* [16] at 300 K at a resolution of 2 cm^{-1} using DFTS are shown in Fig. 4 and listed in Table III. They also published numerical values for n and k for KBr at 100 K. Johnson and Bell [11] also determined the optical constants of KBr at 300 K by reflection DFTS at 2 cm^{-1} resolution, and Palik [28] obtained numerical values by reading their graphs: a selection of these values is also given in Table III, and it can be seen that, as in the case of KCl, there is very good agreement between the two sets of data. Again, the agreement is significantly better than the agreement reported above between the data of Pai *et al.* [16] and Eldridge and Staal [12] for NaCl. Neither set of data for

KBr was corrected for the reference-mirror reflectivity; this again supports the view that differences in the data of Pai *et al.* [16] and Eldridge and Staal [12] for NaCl can be attributed to the corrections which Eldridge and Staal made for the reflectivity of their Al reference mirror. Thus, for measurements with this accuracy, corrections for the imperfect reflectivity of metallized reference mirrors are to be recommended.

KI 4

The far-infrared optical constants of KI determined by Pai *et al.* [16] at 300 K at a resolution of 2 cm^{-1} using DFTS are shown in Fig. 5 and listed in Table IV. They also published numerical values for n and k for KI at 100 K. These values are generally in agreement, within the limits of the experimental uncertainties listed by Pai *et al.* [16], with other determinations of n and k for KI by DFTS reported by Berg and Bell [29] and Memon and Parker [30]. Thomas [31] has presented a critique of KI in this volume using the data in Refs. 16 and 29.

RbCl 5

The far-infrared optical constants of RbCl determined by Pai *et al.* [16] at 300 K at a resolution of 2 cm^{-1} using DFTS are shown in Fig. 6 and listed in Table V. They also published numerical values for n and k for RbCl at 100 K. These are the only values of n and k determined by DFTS for RBCl reported in the literature. As in the case of all the alkali halide crystals studied by Pai *et al.*, the value of ν_{TO} determined from the peak in the conductivity, $\sigma(\nu) = \nu\epsilon''(\nu)/2$, calculated from these results is in good agreement with values reported by Jones *et al.* [32], Wilkinson [33], and Lowndes and Martin [34].

NaF, RbBr, and RbI 6

Pai *et al.* [16] also determined the optical constants of NaF, RbBr, and RbI in the optical phonon region at both 300 K and 100 K by DFTS at a resolution of 2 cm^{-1}. A critique of NaF was published by Ohlídal and Navrátil [35] in *HOC II* using the far-infrared data of Pai *et al.* [16]. The optical constants of RbBr and RbI are reviewed by Ohlídal and Ohlídal [36] and Ohlídal and Franta [37], respectively, elsewhere in this volume.

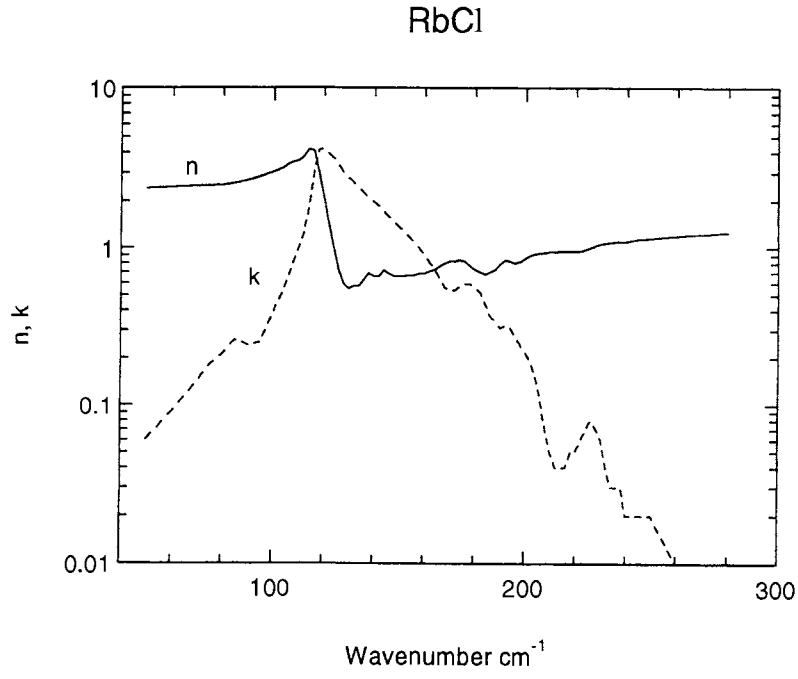

Fig. 6. Log-linear plot of the far-infrared optical constants, n and k, versus wavenumber for RbCl at 300 K. (From Pai *et al.* [16] with permission from the publisher.)

B Semiconductors

Values of n and k measured by reflection DFTS in the far-infrared for the eight semiconductors CdTe, ZnSe, GaP, GaAs, GaSb, InP, InAs, and InSb are listed in Tables VII–XIV and log-linear graphs of the DFTS data are presented in Figs. 7–14. For each of these materials the phonon response has been modelled using a Lorentz model for a damped, simple harmonic oscillator:

$$\epsilon' + i\epsilon'' = (n + ik)^2 = \epsilon_\infty + \frac{\rho \nu_{TO}{}^2}{\nu_{TO}{}^2 - \nu^2 - i\nu\gamma}, \tag{9}$$

where ϵ' and ϵ'' are the real and imaginary parts of the complex dielectric response function, ϵ_∞ is the limiting high frequency value of the real part of the dielectric constant, ν_{TO} is the frequency of the transverse optic phonon mode at the center of the Brillouin zone, γ is the phonon damping parameter, ρ is the dipole strength defined by

$$\rho = \epsilon_0 - \epsilon_\infty, \tag{10}$$

and ϵ_0 is the static dielectric constant.

In the case of the four materials exhibiting free-carrier behavior at frequencies below their reststrahl bands, i.e., GaAs, GaSb, InAs, and InSb, a term has been added to Eq. (9) to account for the plasma response, i.e.,

$$\epsilon' + i\epsilon'' = (n + ik)^2 = \epsilon_\infty + \frac{\rho \nu_{TO}{}^2}{\nu_{TO}{}^2 - \nu^2 - i\nu\gamma} - \frac{\epsilon_\infty \nu_p{}^2}{\nu^2 + i\nu\gamma_p}, \tag{11}$$

where ν_p is the plasma frequency and γ_p is the plasmon damping parameter. The plasma frequency is given by

$$\nu_p{}^2 = \frac{ne^2}{\epsilon_\infty \epsilon_0 m^*}, \tag{12}$$

where n is the free-carrier concentration, e is the charge on the electron, and m^* is the effective mass of the free carriers. For fitting the experimental data, ν_p has been taken as the minimum in the measured amplitude reflectivity. In some cases the plasma frequency lies outside the range of data presented here [25].

The values of the parameters ϵ_0, ϵ_∞, ν_{TO}, γ, ν_p, and γ_p, which are needed to fit the spectra of each of the eight semiconductors, are listed in Table VI. The values of ϵ_0 and ϵ_∞, are taken from Kunc *et al.* [38]. Also listed are the values of the ratio m^*/m_0, where m_0 is the mass of the free-electron, taken from Gray [39] for the four samples which showed free-carrier effects at frequencies below the reststrahl bands.

TABLE VI

Parameters Used in Modelling the Contributions of the Lattice Resonance and the Free Carriers to the Far-Infrared Dielectric Response of Eight Semiconductor Crystals

	ϵ_0	ϵ_∞	ρ	ν_{TO} (cm^{-1})	γ (cm^{-1})	ν_P (cm^{-1})	γ_p (cm^{-1})	m^*/m_0
CdTe	10.2	7.10	3.10	141	6.63	—	—	—
ZnSe	8.80	5.9	2.9	207	6.50	—	—	—
GaP	11.01	9.07	1.945	367	9.0	—	—	—
GaAs	12.80	10.90	1.9	269	6.5	60	35	0.070

InSb	17.77	15.68	2.09	181.0	6.50	75	15	0.015

Numerical values for n and k calculated from Eq. (11) after fitting the model to the experimental data are quoted for comparison throughout each table. Doping has a very large effect on the far-infrared optical constants of semiconductors, not only in the region of the plasma resonance, but also throughout the reststrahl region because of the strong effect of plasmon-LO phonon coupling. This is likely to be the dominant reason for differences between the optical constants of (different) samples measured in different laboratories. The overall agreement between the calculated and measured values of n is generally quite fair throughout the spectrum for most materials. The most notable exceptions to this occur for GaP, InP, and to a lesser extent, GaAs, in the region between ν_{TO} and ν_{LO}, where n is small. In the case of k, reasonable agreement between calculated and measured values is generally found only in the reststrahl and free-carrier regions where k is large. In regions where k is small, a more sophisticated model is required to take account of the effects of additional absorption arising from anharmonicity and the non-linear dipole moment [40, 41]; apart from this, there is a large uncertainty in values of k determined by DFTS in regions where the phase reflection coefficient is small, as mentioned above.

II–VI Semiconductors C

CdTe 1

The far-infrared optical constants of CdTe determined by Maslin *et al.* [24] at 300 K using DFTS at a resolution of 2 cm^{-1} are shown in Fig. 7 and listed in Table VII, where they are compared with values calculated from the oscillator model, Eq. (11) [OM]. The optical constants of CdTe

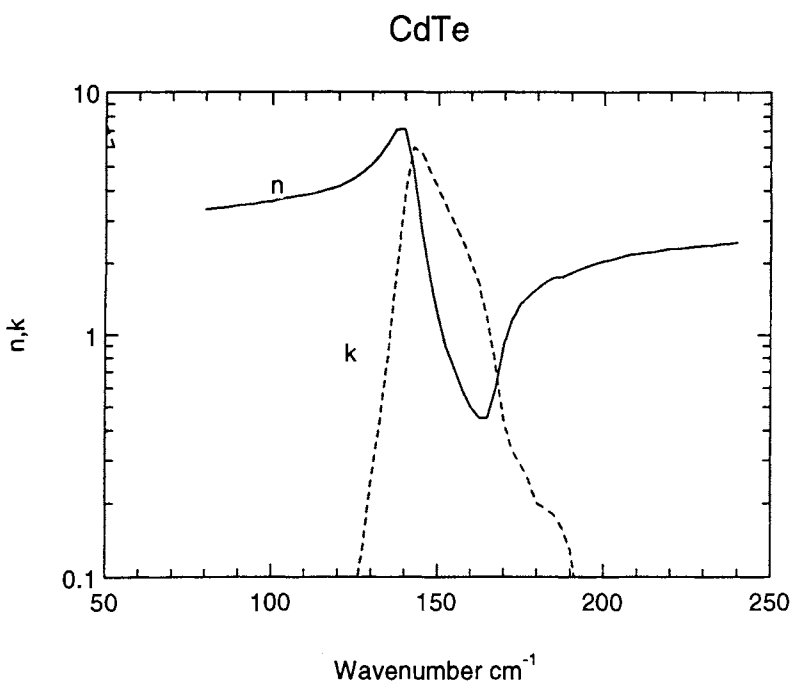

Fig. 7. Log-linear plot of the far-infrared optical constants, n and k, versus wavenumber for CdTe at 300 K.

have also been determined at 300 K using reflection DFTS by Birch and Murray [42] at a resolution of 1 cm^{-1}; their data contained much fine structure a little above the noise level and many features were later assigned by Mok *et al.* [43] as multi-phonon combination bands excited via lattice anharmonicity [40]. Numerical values of n and k read from Birch and Murray's graph by Palik [44] are also listed in Table VII. Differences in the values of n and k in the reststrahl region may be due to the differences in resolution. Apart from this, and poor agreement between the values of k outside the reststrahl region where DFTS is known to be unreliable for measuring k, the overall agreement is reasonable. The transverse optic phonon frequency determined from these data, $\nu_{TO} = 141$ cm^{-1}, is in excellent agreement with previous experimental values; 140.5 cm^{-1} determined by far-infrared reflection-DFTS [42], and 140 cm^{-1} determined by Raman spectroscopy [45] and near-infrared absorption spectroscopy [46]. The longitudinal optic phonon frequency, $\nu_{LO} = 167.5$ cm^{-1}, is in good agreement with previous experimental values for undoped CdTe: 167.5 cm^{-1}, determined by reflection-DFTS [42], and 171 cm^{-1}, determined by Raman spectroscopy [45]; Slack *et al.* [46] carried out an infrared investigation of substitutionally Fe^{2+}-doped CdTe and reported a value of $\nu_{LO} = 180$ cm^{-1}.

2 ZnSe

The far-infrared optical constants of ZnSe determined by Maslin *et al.* [24] at 300 K at a resolution of 4 cm^{-1} using DFTS are shown in Fig. 8 and listed in Table VIII, where they are compared with values calculated from the oscillator model, Eq. (11) [OM], and with values taken from the work of Feldman *et al.* [47], Cardona [48], and Thomas and Hopfield [49], and by Ward [50]. Values of the optical constants of ZnSe determined by transmission DFTS in the millimeter region have been reported by Afsar [51]. Previous data for n and k for ZnSe in the optical phonon region were listed by Ward [50] in *HOC II,* who tabulated the data of Manabe *et al.* [52] and Hattori *et al.* [53]. At frequencies up to about 200 cm^{-1}, i.e., up to the ZnSe transverse optic phonon frequency, the present data for n are in good agreement with the values listed by Ward. Between about 200 and 250 cm^{-1}, where the phase reflection coefficient has its largest values and $r_s(\nu)$ and $\phi_s(\nu)$ change most rapidly, the disagreement with the earlier data is largest, rising to about 60% in n. This is the region in which reflection DFTS is expected to have its greatest advantage. At higher frequencies, the DFTS and reflectivity data for n are again in relatively good agreement (i.e., within

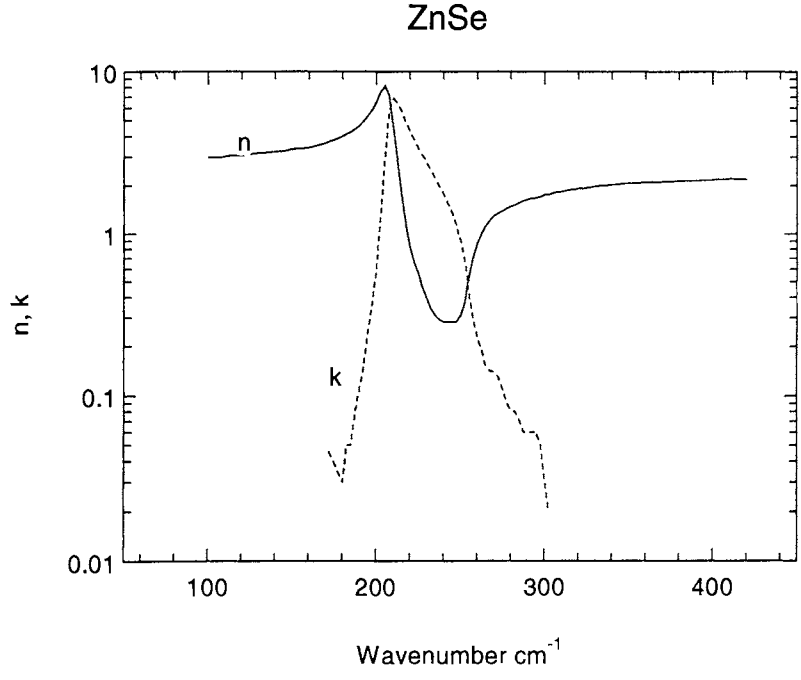

Fig. 8. Log-linear plot of the far-infrared optical constants, n and k, versus wavenumber for ZnSe at 300 K.

a few percent). The transverse and longitudinal optic phonon frequencies determined from these data, $\nu_{TO} = 207$ cm^{-1} and $\nu_{LO} = 253$ cm^{-1}, are in reasonable agreement with previous experimental values of 206 cm^{-1} and 250 cm^{-1}, respectively, determined by Raman spectroscopy [54]. Patel *et al.* [55] have analyzed fine structure and assigned features to phonon combination bands excited via lattice anharmonicity [40].

D III–V Semiconductors

1 GaP

The far-infrared optical constants of GaP determined by Maslin *et al.* [24] at 300 K at a resolution of 4 cm^{-1} using DFTS are shown in Fig. 9 and listed in Table IX, where they are compared with values calculated from the oscillator model, Eq. (11) [OM], and values listed by Borghesi and Guizzetti [56] taken from the work of Barker [57]. The transverse and longitudinal optic phonon frequencies determined from the data of Maslin *et al.*, $\nu_{TO} = 367$ cm^{-1} and $\nu_{LO} = 403$ cm^{-1}, are in good agreement with previ-

ous experimental values: $\nu_{TO} = 366\ cm^{-1}$ and $\nu_{LO} = 402\ cm^{-1}$ determined by far-infrared spectroscopy [58], and $\nu_{TO} = 367\ cm^{-1}$ and $\nu_{LO} = 403\ cm^{-1}$, determined by Raman spectroscopy [59]. No free-carrier response was observable in this sample at frequencies down to 20 cm^{-1} [25].

2 GaAs

The far-infrared optical constants of GaAs determined by Maslin *et al.* [24] at 300 K at a resolution of 4 cm^{-1} using DFTS are shown in Fig. 10

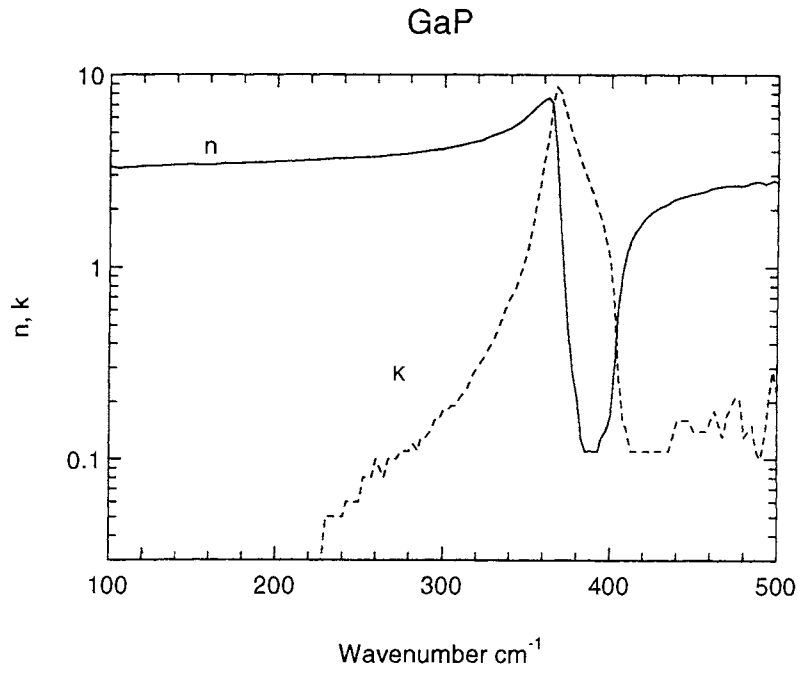

Fig. 9. Log-linear plot of the far-infrared optical constants, n and k, versus wavenumber for GaP at 300 K.

and listed in Table X, where they are compared with values calculated from Eq. (11) [OM] and values of n and k derived from the far-infrared reststrahl work of Kachare *et al.* [60] and Holm *et al.* [61], and values of k determined by Stolen [62], as listed by Palik [63]. Values of the millimeter-wave optical constants of GaAs determined by transmission DFTS have been reported by Afsar and Button [64] and Afsar [65]. The transverse and longitudinal optic phonon frequencies determined from the data of Maslin *et al.*, $\nu_{TO} = 269$ cm^{-1}, and $\nu_{LO} = 293$ cm^{-1}, are in reasonable agreement with previous experimental values, $\nu_{TO} = 269$ cm^{-1} and $\nu_{LO} = 291$ cm^{-1}, determined by Raman spectroscopy [66], and $\nu_{TO} = 271$ cm^{-1} and $\nu_{LO} = 295$ cm^{-1}, determined by far-infrared spectroscopy [67]. The sample was n-type and the onset of the free-carrier response can be seen at frequencies below 150 cm^{-1}. The plasma minimum in the reflectivity occurred at 60 cm^{-1} [25]; using $m^* = 0.07\ m_0$, Table VI [39], the free-carrier concentration is found to be 3.0×10^{16} cm^{-3}. Small differences in the LO frequencies may arise from differences in plasmon-LO phonon coupling for samples with different carrier concentrations.

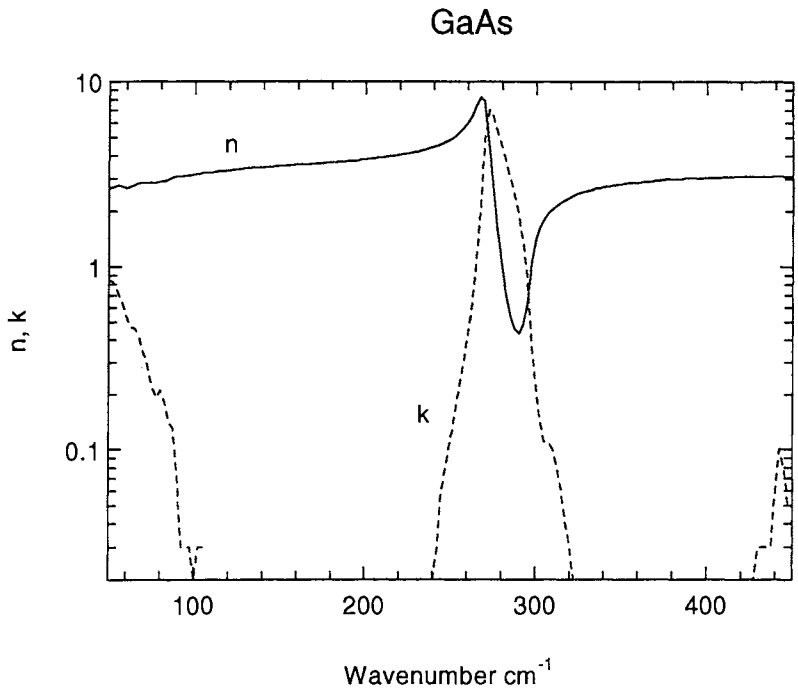

Fig. 10. Log-linear plot of the far-infrared optical constants, n and k, versus wavenumber for GaAs at 300 K.

3 GaSb

The far-infrared optical constants of GaSb determined by Maslin *et al.* [24] at 300 K at a resolution of 4 cm^{-1} using DFTS are shown in Fig. 11 and listed in Table XI, where they are compared with values calculated from the oscillator model, Eq. (11) [OM]. Hass and Henvis [68] measured the fundamental lattice reflection bands of several III-V semiconductors, including GaSb, at liquid-helium temperature and fitted a classical, damped harmonic oscillator model to their data. Edwards and White [69] have listed values of n and k for GaSb at liquid-helium temperature calculated from this model, but no previous numerical values for n and k for GaSb at 300 K have been found in the literature. The sample measured by Maslin *et al.* was n-type, and the onset of the free-carrier plasma response can be seen in Fig. 11 at frequencies below about 150 cm^{-1}. The presence of free carriers will modify the optical constants of the sample throughout the optical-phonon region, making it difficult to compare data for different samples. The transverse and longitudinal optic phonon frequencies determined from the data of Maslin *et al.*, ν_{TO} = 227.5 cm^{-1}, and ν_{LO} = 237.5 cm^{-1}, are in reason-

Pettit and Turner [74], measured for an *n*-type sample with a carrier density of 5×10^{16} cm^{-3}. The values of k were calculated by Glembocki and Piller [72] using an oscillator model, with optical-phonon frequencies taken from Mooradian and Wright [75] and ϵ_∞ taken from Hass [76]. The transverse and longitudinal optic phonon frequencies determined from the data of Maslin *et al.*, $\nu_{TO} = 304$ cm^{-1}, and $\nu_{LO} = 346.5$ cm^{-1}, are in excellent agreement with previous experimental values, $\nu_{TO} = 304.5$ cm^{-1} and $\nu_{LO} = 346.4$ cm^{-1}, determined by Raman spectroscopy [77]. No free-carrier response was observable in this sample at frequencies down to 25 cm^{-1}, which puts an upper limit on the (*n*-type) free-carrier concentration of 7×10^{15} cm^{-3}.

5 InAs

The far-infrared optical constants of InAs determined by Maslin *et al.* [24] at 300 K at a resolution of 4 cm^{-1} using DFTS are shown in Fig. 13 and listed in Table XIII, where they are compared with values calculated from

the oscillator model, Eq. (11) [OM]. The far-infrared optical constants of InAs determined by reflection DFTS were previously reported by Gast and Genzel [78]. The transverse optic phonon frequency determined from these data, $\nu_{TO} = 218.5\ cm^{-1}$, is in good agreement with a previous experimental value, 217.3 cm^{-1}, determined by Raman spectroscopy [79]. The longitudinal optic phonon frequency, $\nu_{LO} = 242.5\ cm^{-1}$, is somewhat higher than a previous experimental value, 238.6 cm^{-1}, determined by Raman spectroscopy [79]. The plasma minimum in the reflectivity occurred at 71 cm^{-1} [25]; using $m^* = 0.026\ m_0$, Table VI [39], the free-carrier concentration is found from Eq. (12) to be $1.8 \times 10^{16}\ cm^{-3}$. Small differences in the LO frequencies may arise from differences in plasmon-LO phonon coupling for samples with different carrier concentrations. Also shown in the table are values of n and k determined by Memon *et al.* [80] for a different sample by DFTS. There are significant differences in the reststrahl region, particularly in the region of ν_{LO} which may also be due to different plasmon-phonon coupling in the two samples.

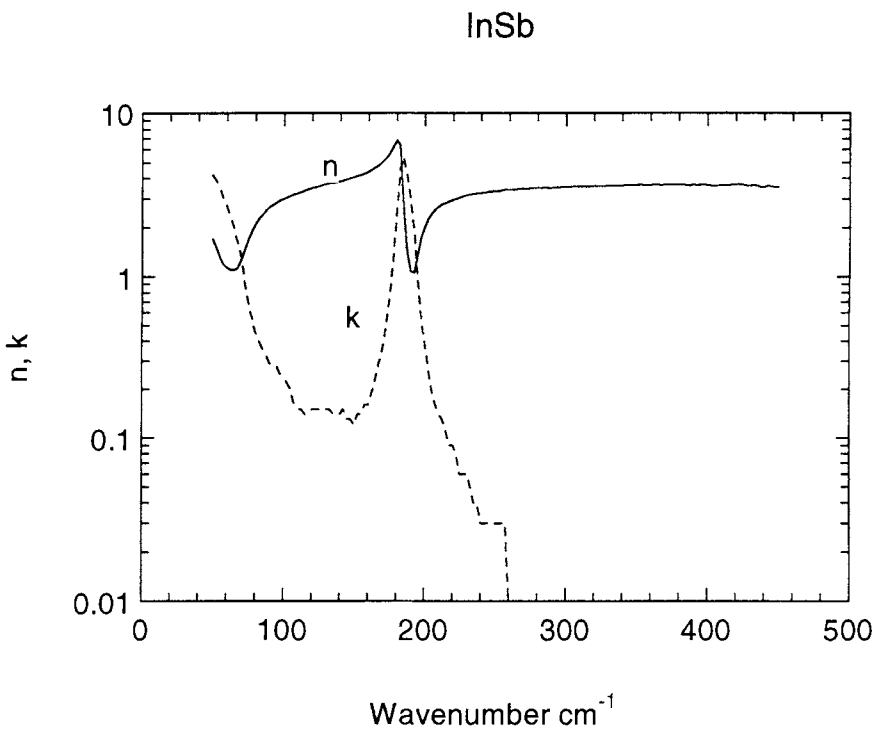

Fig. 14. Log-linear plot of the far-infrared optical constants, n and k, versus wavenumber for InSb at 300 K.

InSb 6

The far-infrared optical constants of InSb determined by Maslin *et al.* [24] at 300 K at a resolution of 4 cm^{-1} using DFTS are shown in Fig. 14 and listed in Table XIV where they are compared with values calculated from the oscillator model, Eq. (11) [OM], and the data of Sanderson [81] as listed by Holm [82]. Measurements of the far-infrared optical constants of InSb determined by reflection DFTS have also been reported by Gast and Genzel [78] and Afsar *et al.* [83]. The transverse optic and longitudinal optic phonon frequencies determined from the data of Maslin *et al.*, $\nu_{TO} = 181$ cm^{-1}, and $\nu_{LO} = 193$ cm^{-1}, are in excellent agreement with previous experimental values, $\nu_{TO} = 182.4$ cm^{-1}, and $\nu_{LO} = 193.0$ cm^{-1}, determined by Raman spectroscopy [84]. The plasma minimum in the reflectivity occurred at 75 cm^{-1} [25]; using $m^* = 0.015\ m_0$, Table VI [39], the free-carrier concentration is found from Eq. (12) to be 1.5×10^{16} cm^{-3}. Small differences in the LO frequencies may arise from differences in plasmon-LO phonon coupling for samples with different carrier concentrations.

INTRODUCTION I

Photothermal- and photoacoustic-based spectroscopic techniques have proliferated in recent years as primary methodologies for measuring the optical absorption coefficient, α, in broad ranges of solids, which may, or may not, be easily measurable by other, more conventional spectroscopic techniques. An increasing body of literature concerning these measurements can be consulted by the interested reader, including a number of monographs, review books and treatises on the state-of-the-art in these fields [1–7]. It should be noted that the foregoing techniques are now widely used to measure *directly* the optical absorption coefficient $\alpha(\lambda)$ from a dynamic measurement of the heat released *via* the spatial rate of optical-to-thermal energy conversion in a material, rather than the extinction coefficient, $k(\lambda)$.

HANDBOOK OF OPTICAL CONSTANTS OF SOLIDS III

The two measurements are, of course, equivalent and are related through the defining equation of the former

$$\alpha(\lambda) = 4\pi k(\lambda)/\lambda \qquad [\text{cm}^{-1}]. \tag{1}$$

As a result of this peculiarity of the photoacoustic/photothermal techniques, all the spectroscopic plots and data to be discussed in this chapter will be given in terms of $\alpha(\lambda)$. The major α-measuring methodologies in this field include in order of historical sequence a) gas-cell and piezoelectric photoacoustic spectroscopy (PAS); various photothermal spectroscopies (PTS), such as b) photothermal beam-deflection spectroscopy (PDS), otherwise known as Mirage-Effect spectroscopy; c) Fourier-transform infrared photoacoustic (FTIR-PAS) spectroscopies; and d) photopyroelectric spectroscopy (PPES). The PDS family of techniques has been well described by Briggs in Chapter 4 and, therefore, will not be discussed further in this chapter, except where necessary for complementary measurements of α, especially with regard to semiconducting amorphous thin-films. Again, for historical reasons the presentation of the material in this chapter will be done as follows: i) technique description and instrumental implementation; and ii) applications to optical-property measurements of semiconductors, specifically of α at a single wavelength or within a spectral range.

II PHOTOACOUSTIC SPECTROSCOPY (PAS)

A Gas-Cell—Microphone Photoacoustics

The photoacoustic effect in solids was first described quantitatively by Parker [8] in 1973 and was later generalized by what has come to be known as the "Rosencwaig–Gersho (RG) Theory" [9]. Figure 1 shows a cross-section of a typical photoacoustic cell used for the measurement of α in sol-

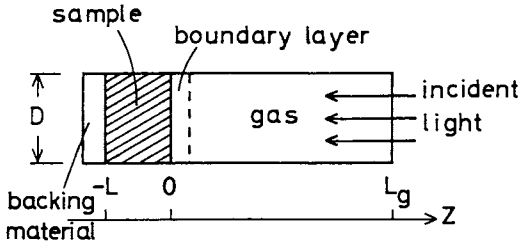

Fig. 1. Cross-sectional view of a simple cylindrical photoacoustic cell. (From Rosencwaig and Gersho [9] with permission from the publisher.)

ids. The gas-cell—microphone PA signal is generated as an acoustic disturbance in a hermetically sealed chamber equipped with a sensitive microphone, following the incidence and absorption of optical power by a solid sample inside the acoustic chamber. The incident radiation penetrates the cell through a transparent window, and the intensity is mechanically chopped or otherwise modulated at a constant frequency $f = \omega/2\pi$. The absorbed radiation is subsequently converted into heat through non-radiative relaxation mechanisms in the bulk and/or at the surface of the solid. Conduction heat transfer to the surrounding gaseous medium (air) at the frequency f is almost always the predominant energy-transport process and the one that generates the harmonic acoustic disturbance detected by the sensitive microphone. The absorption of photons by a solid followed by energy conversion and de-excitation pathways is described schematically in Fig. 2. Non-radiative conversion is but one such pathway, which, nevertheless, is usually the dominant de-excitation mechanism in solids, leading to production of heat. Other possible energy transformations and conversions are also shown in Fig. 2. The PA signal from the microphone is demodulated by a lock-in amplifier, and the amplitude and phase are stored and displayed on a computer screen for quantitative analysis. A typical experimental set-up is shown in Fig. 3.

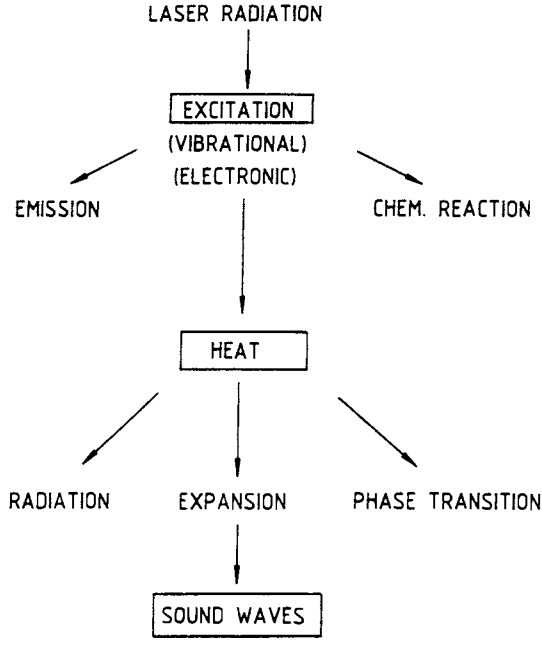

Fig. 2. Optical energy conversion pathways in a photoacoustic experiment.

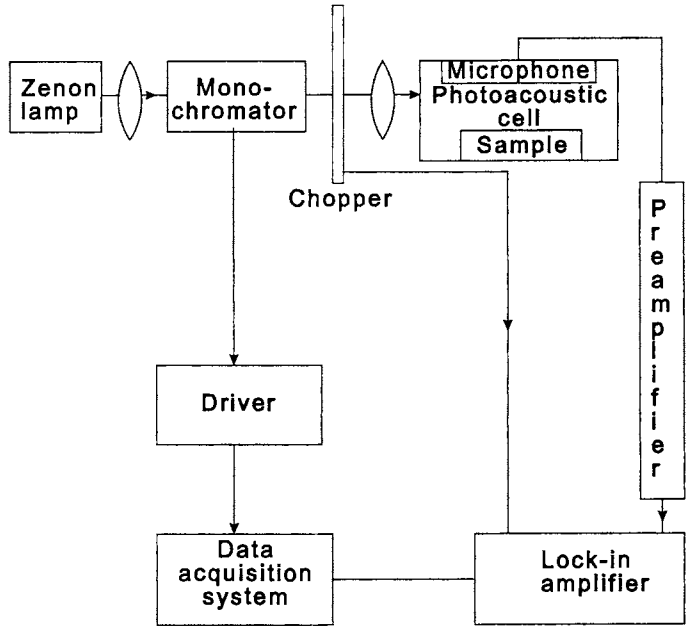

Fig. 3. Typical experimental set-up for gas-cell—microphone PAS of solids.

Assuming a spatially broad, homogeneous and isotropic, sinusoidally chopped/modulated monochromatic light source with wavelength, λ, impinging on an absorbing solid of optical absorption coefficient, $\alpha(\lambda)$, with intensity

$$I(t) = \frac{1}{2} I_0(1 + \cos\omega t) \qquad [\mathrm{W/cm^2}], \tag{2}$$

the heat density produced at depth x from the surface of the solid is given by

$$Q(x,t) = \frac{1}{2}\alpha I_0 e^{-\alpha x} Re(1 + e^{i\omega t}) \qquad [\mathrm{W/cm^3}]. \tag{3}$$

Coupled heat-diffusion equations in the gas, solid, and backing regions of Fig. 1 can be solved to give the a.c. temperature oscillation in the PA chamber [9]. This is the thermal-wave responsible for the acoustic oscillation (the pressure wave) detected by the microphone. From the real and imaginary parts of the complex thermal-wave signal *at the surface of the solid,* the PA signal expressions are worked out in the RG theory assuming the validity of the ideal gas law and the adiabatic gas law in the hermetically sealed

chamber/cell. The PA amplitude and phase can thus be calculated in the general case from the real and imaginary parts of the signal. These are complicated expressions, and they are generally non-linear in the parameter α. Nevertheless, substantial simplifications occur in a number of limiting cases of the RG theory:

Optically Transparent Solids ($\alpha^{-1} > L$)

Case 1a: Thermally Thin Solids ($\mu > L$; $\mu >$ or $< \alpha^{-1}$): The symbol μ, a function of the chopping frequency, stands for the thermal-wave penetration depth in the solid material of thickness L,

$$\mu(\omega) = \sqrt{2\beta/\omega}, \tag{4}$$

where β is the thermal diffusivity of the sample [cm^2/s]. In this limiting case, the optical radiation is assumed to obey the Beer-Lambert Law and is absorbed throughout the length of the solid. A fraction of it exits the back surface of the sample and impinges on the backing material, which is assumed to be transparent and of infinite thickness. In this limit, whether $\alpha >$ or $< \sqrt{2}/\mu(\omega)$, the complex magnitude of the PA signal is approximately given by

$$Q \approx Y\mu_g(\mu_b/\kappa_b)Y\frac{(1-i)\alpha L}{2}, \tag{5}$$

where the subscript *"b"* indicates the backing material, *"g"* indicates the surrounding gas (almost always air), κ stands for thermal conductivity [W/cm K], μ_j has the definition of Eq. (4) for $j = g$ or b. Y is a constant (real) pre-factor independent of the optical absorption coefficient of the sample, but generally dependent on wavelength through its linear dependence on the reflectivity in the form $[1 - R(\lambda)]$. Equation (5) shows that the PA signal in this limit is proportional to αL and inversely proportional to ω. Furthermore, the thermal properties of the backing play a role in this thermally thin situation.

Case 1b: Thermally Thick Solids ($\mu < L$; $\mu \ll \alpha^{-1}$): The complex magnitude of the PA signal is now approximated by

$$Q \approx -iY\mu_g(\mu/\kappa)\frac{\alpha\mu}{2}. \tag{6}$$

Here the signal is proportional to $\alpha\mu$, rather than αL, that is only the radiation that is absorbed within the optical absorption length α^{-1} contributes to the signal, even though optical absorption takes place throughout the thickness of the sample. Since the sample is now thermally "thick", the thermal properties of the backing material have been replaced by those of the solid, and the frequency dependence is $\omega^{-3/2}$.

Optically Opaque Solids ($\alpha^{-1} \ll L$)

Case 2a: Thermally Thin Solids ($\mu \gg L$, $\mu \gg \alpha^{-1}$): In this case the Beer-Lambert Law yields $e^{-\alpha L} \approx 0$, and the complex magnitude of the PA signal becomes

$$Q \approx Y(\mu/\kappa) \frac{(1-i)\mu_g}{2}. \tag{7}$$

In this case, the signal is independent of the optical absorption coefficient (*photoacoustic saturation*) and decreases with increasing frequency as ω^{-1}. No spectroscopic information can be derived in this limit.

Case 2b: Thermally Thick Solids ($\mu < L$, $\mu > \alpha^{-1}$): When the modulation/chopping frequency rises well above the limits represented in Case 2a, the PA signal becomes

$$Q \approx Y\mu_g(\mu/\kappa) \frac{(1-i)}{2}. \tag{8}$$

Again, this case lies within the range of photoacoustic saturation, and no spectroscopic information may be derived from experiments in this (intermediate) frequency range.

Case 2c: Thermally Thick Solids ($\mu \ll L$, $\mu < \alpha^{-1}$): This situation obtains at very high frequencies, so that the sample is entirely thermally thick, and the PA signal comes out of photoacoustic saturation with frequency dependence $\omega^{-3/2}$:

$$Q \approx -Y\mu_g(\mu/\kappa) \frac{\alpha\mu}{2}. \tag{9}$$

Even though theoretically this is a legitimate special case where PAS operates as an absorption spectroscopy, in practice the modulation frequencies required to satisfy the conditions of the case may be too high to yield an acceptable signal-to-noise ratio.

B Piezoelectric Photoacoustics

In the case of gas-microphone PA detection, the optically generated heat is coupled to the non-absorbing gas of the sample chamber, and the ensuing time-dependent pressure fluctuation is detected by a sensitive microphone. An alternative signal-transduction methodology is through coupling of the thermal energy released following optical absorption to the vibrational modes of the sample, i.e., through coupling to its acoustic phonon spectrum. In this

thermoelastic mode, the speed of energy transfer is governed by the speed of sound and is limited by the sample/transducer geometry and the boundary conditions at the sample-gas and sample-transducer interfaces. The thermoelastic theory of this PAS mode has been presented adequately by White [10]. The generated harmonic pressure pulse in the sample is communicated to an intimately attached piezoelectric transducer. This pressure pulse results in a harmonic electrical signal across the piezoelectric transducer, which may be demodulated by a lock-in amplifier (LIA) as in the case of gas-cell—microphone PAS. A more complete theory directly applicable to piezoelectric PAS of condensed matter was developed by Jackson and Amer [11], commonly known as the "Jackson–Amer (JA) model." A simple outline of this detection principle is shown in Fig. 4. The expansion of the central region causes displacement of the sample surface by two separate mechanisms. First, the enlargement of the central region causes the general expansion of both surfaces of the sample at $z = 0$ and $z = L$, Fig. 4(a). Second, in the case of strongly absorbing solids, the heat in the illuminated region decays spatially throughout the thickness of the sample; consequently, the front part of the sample expands more than the rear part, resulting in bending, Fig. 4(b). Such bending compresses the rear surface at $z = L$ and causes further expansion to the front surface, which adds to the general expansion. These displacements of the sample surfaces are sensed by a sufficiently thin piezoelectric transducer, the generated voltage being detected by appropriate electrodes.

The general expression of the piezoelectric PA signal is quite complicated

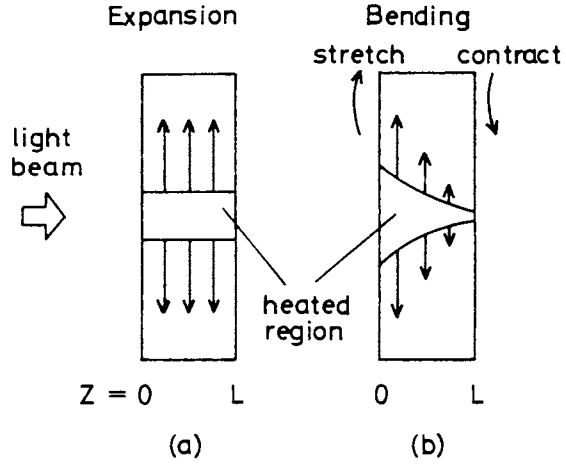

Fig. 4. Sources of surface strain for the average expansion (a) or bending (b) of an irradiated absorbing solid. The PA piezoelectric transducer may be attached to either side of the sample. (From Jackson and Amer [11] with permission from the publisher.)

and hard to interpret physically. For lucidity, Jackson and Amer [11] worked out a few special cases of the JA model, neglecting the surface thermal conduction of the solid to the surrounding gas and considering sample-parameter-limiting situations similar to those presented in the RG model. For front-surface illumination of a solid sample ($z = 0$) and the piezoelectric transducer at $z = L$, a convenient form of these special cases was given by Ikari *et al.* [12]

Optically opaque solids:

Case 1a: Thermally Thick Solid:

The complex magnitude of the PA signal is given by

$$Q \approx -\frac{2MPa_t}{i\omega L\rho_s C_s}, \tag{10}$$

where a_t is the linear expansion coefficient of the solid, P is the incident power corrected for the sample reflectivity $R(\lambda)$; M is a constant calculated by means of piezoelectric and dielectric constants; and ρ_s, C_s are the density and specific heat capacity of the solid, respectively.

Case 1b: Thermally Thin Solid: In this situation the complex signal is

$$Q \approx \frac{MPa_t}{i\omega L\rho_s C_s}. \tag{11}$$

Optically transparent solids:

In the thermally thick limit the expression for the PA signal is an explicit function of the optical absorption coefficient

$$Q \approx \frac{MPa_t}{i\omega L\rho_s C_s}\left[1 - e^{-\alpha L} \pm (6/L\alpha)[1 - (L\alpha/2) - e^{-\alpha L}(1 + L\alpha/2)]\right]. \tag{12}$$

The negative sign applies in the case where the transducer is away from the optical beam ($z = L$), and the positive sign is applicable when the transducer is toward the beam ($z = 0$).

In terms of the utility of piezoelectric PAS as a spectroscopic tool for the measurement of α, Eq. (12) shows that for small values of α the signal is directly proportional to this parameter. For high values of α, however, the position of the piezoelectric with respect to the incident beam yields significantly different results: In the position $z = L$, as α increases the signal decreases, eventually passing through zero and changing sign at higher values of α. In this limit, the bending compression exceeds the expansion due to heating. On the other hand, in the position $z = 0$, the signal shows little photoacoustic saturation up to some very high values of α. In this case the bending and the expansion terms add, thus increasing the observed signal.

From the foregoing discussion it is apparent that the mechanism generat-

ing the PA signal is greatly dependent on the position of the transducer, and the resulting spectra are frequently too complicated to understand quantitatively. The peaks and valleys in the spectra are sometimes inverted as well [13]. An alternative spectroscopic technique using a pyroelectric element [14] has been developed to detect photothermal waves in solids [15]. Photopyroelectric spectroscopy has distinct advantages over piezoelectric PAS, such as the simplicity of calibration, insensitivity to acoustic noise and mechanical resonances, a high potential for signal-to-noise-ratio improvement, and a flat response in the range 0.1 to 10^{-7} K/s. This technique has been useful for solids exhibiting complicated PA spectra.

PHOTOPYROELECTRIC SPECTROSCOPY (PPES) III

A one-dimensional geometry of a PPE system is shown in Fig. 5 [15]. The sample is in intimate contact with a pyroelectric transducer, most likely a thin polyvinylidene fluoride film (PVDF) of thickness ℓ. The pyroelectric

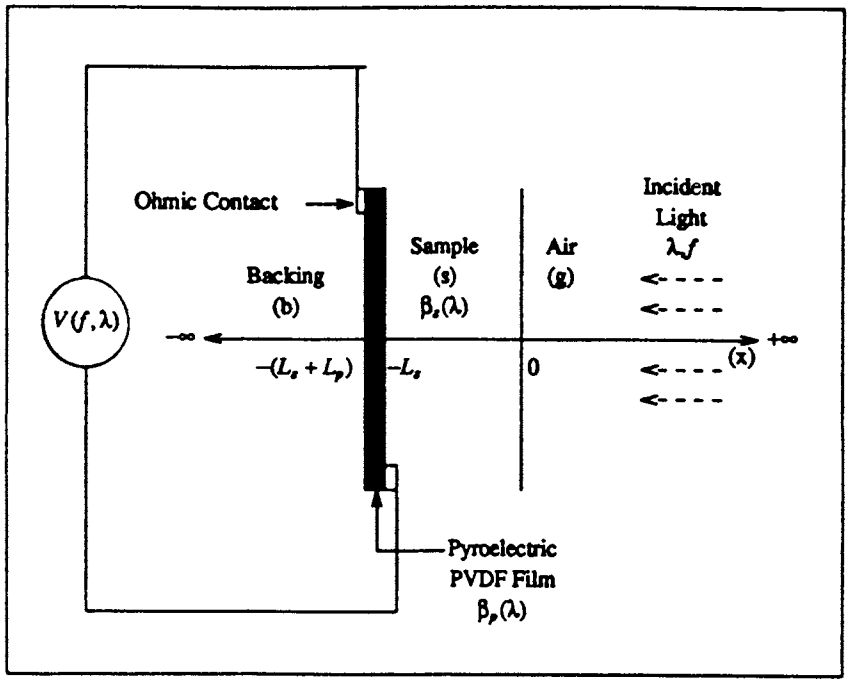

Fig. 5. One-dimensional geometry of a frequency-domain photopyroelectric system. (From Mandelis and Zver [15] with permission from the publisher.)

coefficient of the detector is p. The sample/transducer system is supported by a transparent (semi-infinite) backing material. The PPE cell, unlike the PA cell, does not require hermetic closure (open geometry). Light absorption by the sample and nonradiative energy conversion to heat increases the temperature of the pyroelectric thin-film transducer. This temperature increase results in a potential difference between the upper and lower surfaces of the transducer due to the pyroelectric effect [14]. This voltage $V[\omega, \alpha(\lambda)]$ amounts to an electrical signal, which is measured in the external circuit through the connection of Ohmic leads to the pyroelectric as shown in Fig. 5. The demodulation of the PPE voltage is done in a manner similar to that used for PAS, and the rest of the experimental system is also similar. The charge accumulated in the pyroelectric due to a change $T_p(t)$ in temperature is given by

$$q(t) = pT_p(t). \tag{13}$$

The PPE voltage across the transducer electrodes is

$$V(\omega,\alpha) = \frac{i\omega A < T_p(\omega,\alpha) > R}{(1 + i\omega\tau_E)}, \tag{14}$$

where A is the area of the pyroelectric exposed to temperature variation, R is the total resistance of the equivalent circuit, and τ_E is the RC time constant of the equivalent circuit [16]. The average value of the pyroelectric temperature oscillation is taken over the thickness of the pyroelectric element:

$$< T_p(\omega,\alpha) > = \frac{1}{\ell} \int_{\ell} T_p(x;\omega,\alpha)\, dx. \tag{15}$$

The expression for the average thermal-wave field across the pyroelectric is given by a treatment of coupled heat-diffusion equations similar to that derived for PAS [9]. For practical spectroscopic applications, Mandelis and Zver have developed a one-dimensional PPE model, valid for broad optical-excitation beams compared to both sample thickness and pyroelectric-element thickness, and known as the "Mandelis–Zver (MZ) model" [15]. In terms of the ability of the technique to measure optical absorption coefficients, a more extensive analysis of the signals has also been conducted by Chirtoc and Mihailescu [17]. According to the MZ model, the PPE signal depends linearly on the sample optical absorption coefficient

$$V(\omega,\alpha) \propto \alpha, \tag{16}$$

when *the sample is optically opaque,* $\alpha^{-1} \ll L$, *and thermally thick,* a case likely to occur at high modulation/chopping frequencies, such that $\mu << L$

and $\mu < \alpha^{-1}$. The signal magnitude, however, decreases exponentially with the square root of modulation frequency, $\exp(-L/\mu)$; therefore, the signal-to-noise ratio (SNR) is expected to be poor.

When the sample is *optically transparent,* $\alpha^{-1} > L$, *and thermally thick,* this case is of strong experimental interest, because the complex magnitude of the PPE signal is

$$V(\omega,\alpha) \propto 1 - \alpha L, \tag{17}$$

and the signal decreases only as ω^{-1}, so the SNR is expected to be satisfactory. This limit is achieved when $\mu < L$ and $\mu \ll \alpha^{-1}$. The two foregoing cases are the only ones which can yield direct spectroscopic information about the optical absorption coefficient of the sample material, as the result of thermal and optical transmission, respectively [18, 19].

IV MEASUREMENTS OF $\alpha(\lambda)$ IN SEMICONDUCTORS USING PHOTOACOUSTIC/PHOTOTHERMAL TECHNIQUES

In this section, several examples will be given of optical absorption spectra of simple semiconducting solids, which have been measured by means of photoacoustic or photothermal techniques. The selection of this particular family of solids is in order to keep the volume of material in this chapter within reason as a first photothermal/photoacoustic presentation in the *Handbook of Optical Constants of Solids* series, and reflects the extraordinary importance of these materials in science and technology in the 1990s. The major advantage of the methodologies discussed in Sects. I–III over their purely optical spectroscopic counterparts, is the superior dynamic range of the former, especially at low α ranges. This stems from the linear dependence of the photothermal signals on α (or αL in the case of thin layers), which renders the signal proportional to the thermal energy released following absorption, as opposed to optical reflectance or transmittance detection: in the former situation the transducer only registers the amount of converted thermal energy which is proportional to α; in the latter situation, two large optical signals must be subtracted (incident − transmitted energy) to calculate the amount absorbed and thus to estimate α. This subtraction procedure becomes increasingly less accurate as α decreases toward zero, and it is in this range where PAS, PPES, and PDS excel as zero-baseline spectroscopies. An excellent discussion of this crucial aspect of the photoacoustic/photothermal spectroscopies has been given by Boccara and Fournier [20]. Absolute measurements of α can be obtained using photoacoustic and photothermal methods, by normalizing sample spectra by the spectrum of a totally optically

opaque (reference) material. Such a spectrum is photothermally saturated [9, 19]; therefore, it is independent of the absorption coefficient of the reference and its spectral signature depends solely on the optical fluence of the source and on the thermal/acoustic and signal transduction characteristics of the sample chamber and the instrumentation. Quantitative $\alpha(\lambda)$ spectra of a material may be obtained from the ratio of the signal amplitude with that of the reference, and from the difference of the signal phase from the phase of the reference (normalization). Xerox toner is the usual reference material in the photoacoustic literature.

The PA or PT spectra in this section will be presented or discussed according to the following rules: 1) Quantitative spectra of α (cm^{-1}) will be presented from the original reference(s), whereas qualitative-only spectra will be briefly discussed and references will be given; 2) Spectra of semiconductors whose optical spectra (α, k, or n) have already appeared in the *HOC I, II,* or *III* will be given priority over other spectra. Historically, the complementary nature of PAS or PTS to optical spectroscopies has manifested itself through the measurement of spectra of materials in states complementary to those conventionally measured (e.g., powders instead of single crystals). Furthermore, the high dynamic range of the PAS or PTS signals has been taken advantage of in extending the low spectral (or α) ranges beyond those conventionally measured by optical techniques.

1 Si

Qualitative measurements of gas-cell microphonic PA spectra of Si in the 200–1200 nm region were performed by Tokumoto *et al.* [21]. The measurements were performed at low chopping frequencies so as to be in the thermally thin regime. An abrupt change was observed at 1100 nm (1.12 eV) which corresponds to the fundamental absorption edge, E_G. In the above-band-gap regime (photoacoustic saturation region) the only wavelength-dependent term of the PA signal is the $[1\text{-}R(\lambda)]$ factor embedded in Y, Eq. (7) or Eq. (8). Good correlation of the observed "dips" with optical reflectance spectra was found, thus verifying the origin of these features in the electronic band structure of Si. Ram *et al.* [22] recorded qualitative gas-cell—microphone PA spectra of powdered Si in the range 800–1300 nm and estimated the value of E_G to be 1.18 eV $\pm$ 0.01 eV. Quantitative $\alpha(\lambda)$ spectra of a 400 μm-thick crystalline Si wafer were obtained by Christofides *et al.* [23] using PPES. These authors used both PPE amplitude and phase data and the MZ theory to determine α from a single-modulation-frequency experiment in the range 1100–1400 nm: this procedure allowed the unambiguous determination of α at several frequencies in regimes intermediate between thermally thin and thick. The resulting spectra are shown in Fig. 6 [23–25].

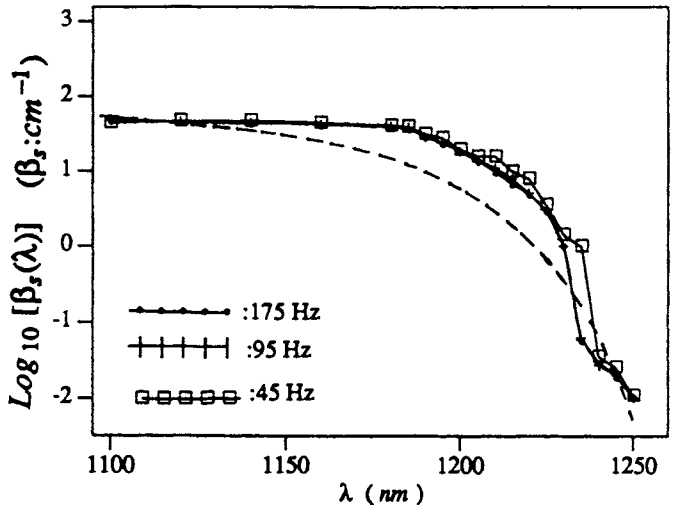

Fig. 6. Logarithm of the optical-absorption-spectrum calculation for Si. Data were taken from several PPE amplitude and phase data sets at 45, 95, and 175 Hz. Flatness in the short wavelength region is due to PPE saturation. The dashed curve is from Sze [24] and Kirev [25]. (From Christofides *et al.* [23] with permission from the publisher.)

Ge 2

Tokumoto *et al.* [21] presented a qualitative gas-cell PA spectrum of Ge in the 200–1000 nm region. Above-bandgap features due to the spectral variation of the reflectance were observed in the PA amplitude and were well correlated to optical reflectance spectra. Welsch *et al.* [26] used a thermoelastic variant of photothermal deflection spectroscopy (see Chapter 4), developed by Olmstead *et al.* [27] to obtain the absorption coefficient of a thin-film Ge sample at 10.6 μm, as characteristic of IR optical-component absorption. They found α_{Ge} (10.6 μm) = 0.0019 cm^{-1}. Fig. 7 shows quantitative $\alpha = \beta_s(\lambda)$ spectra of a wafer of crystalline Ge obtained using PPES at various chopping frequencies in the thermally thin limit of Eq. (17) [28]. Real-time spectrum normalization by the Xe-lamp throughput was employed. The high-energy flat regions are due to PPE saturation: this phenomenon sets in at ~ 1850 nm for the 14 Hz spectrum and at 1800 nm for the higher-chopping-frequency spectra. The very reproducible absorption feature centered at 1933 nm does not appear in the conventional optical transmission spectra of Ge [24,25]. It is believed to be a surface damage or contamination feature as a result of the fabrication and polishing process. This feature does not appear in the PPE phases corresponding to Fig. 7 (not shown), and such a correlation between amplitude and phase spectra would be expected from absorption features homogeneously distributed throughout the wafer

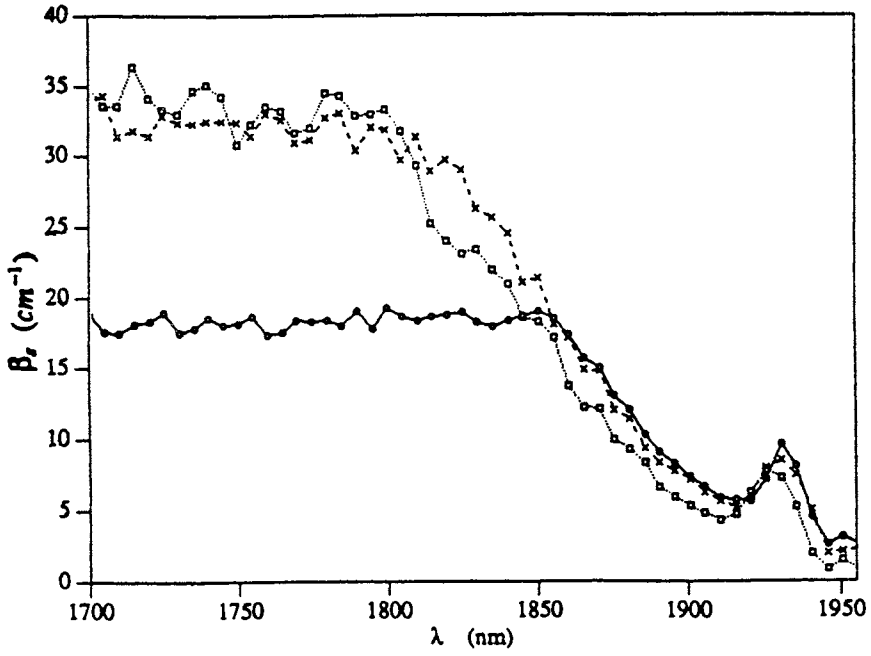

Fig. 7. Optical-absorption-coefficient $\alpha = \beta_s(\lambda)$ calculation for Ge as a function of wavelength. Data taken at various frequencies: - • - : 14 Hz; - x - : 41 Hz; - □ - : 75 Hz. (From Christofides *et al.* [28] with permission from the publisher.)

bulk according to the MZ theory [15]. Assuming a parabolic density-of-states approximation of the conduction-band structure of Ge, a plot of $\sqrt{\alpha h\nu}$ vs. photon energy E and a least-squares fit to the straight line obtained from the $f = 75$ Hz spectrum of Fig. 7, yielded an intercept which gave the energy-gap value for germanium [28] $E_G = 0.652$ eV. This value is in agreement with the one previously reported [24, 25].

3 AgCl

Low and Parodi [29] have used a home-made, single-beam, dispersive infrared PA spectrometer constructed from a Perkin-Elmer Model 421 bed and Model 421 or 621 interchange to obtain spectra of several inorganic solids, including AgCl in the 4000–800 cm^{-1} region. The spectra were normalized by that of carbon black and were presented in qualitative units as ratios of PA signals. Other IR spectra studied by these authors include aspirin, polyethylene, sucrose, siloxane, $BaI_2 \cdot 2H_2O$, KNO_4, $CaSO_4$, KBr, MgO, S, Cu_2O, and Ag_2S.

ZnS 4

Welsch *et al.* [26], using the thermoelastic variant of PDS developed by Olmstead *et al.* [27], measured the absorption coefficient of a thin-film of ZnS at 10.6 μm:

$$\alpha_{ZnS} = 0.18 \text{ cm}^{-1}$$

Rosencwaig [30] measured the qualitative gas-cell—microphonic PA spectrum of ZnS and obtained the band-gap value of 3.7 eV, compared with 3.6 eV from specular-reflectance measurements. Ram *et al.* [22] repeated those measurements with the same technique and estimated a value of 3.81 eV at room temperature. The *Handbook of Chemistry and Physics* value of E_G for ZnS is 3.67 eV [31].

ZnSe 5

The optical absorption coefficient of ZnSe has been measured at 10.6 μm by Welsch *et al.* [26] as discussed above, and by Fernelius [32] who fitted gas-cell—microphone PA frequency responses from a ZnSe window with an AR coating to a two-layer extension [33, 34] to the RG theory [9]. The results are

$$\alpha_{ZnSe} = 0.0055 \text{ cm}^{-1} \quad \text{(Thin-film; Welsch et al. [26])}$$

$$\alpha_{ZnSe} = 0.0064 \text{ cm}^{-1} \quad \text{(Bulk laser window; Fernelius [32]).}$$

Fernelius also measured an uncoated CVD ZnSe window [35] using the same technique. He found

$$\alpha_{CVD\text{-}ZnSe} = 4.06 \times 10^{-3} \text{ cm}^{-1}.$$

CdTe 6

The bandgap energy of this semiconductor at room temperature has been measured from the gas-cell microphonic PA spectrum by several investigators:

$$E_G = 1.58 \text{ eV} \quad \text{(Ram } et\ al. \text{ [22])}$$

$$E_G = 1.50 \text{ eV} \quad \text{(Nicolic and Todorovic [36]).}$$

These values compare well with the conventional value [31] of 1.50 eV.

7 GaAs

Microphonic PA measurements in the saturation region of III–V semiconducting GaAs samples lapped by alumina powder and etched by appropriate etchants, were measured by Tokumoto *et al.* [21]. This qualitative spectrum was shown to correlate well with the calculated $1 - R(\lambda)$ spectrum as expected in the optically opaque regime, and yielded the value $E_G = 1.43$ eV. Ikari *et al.* [37] performed piezoelectric PA measurements on 530–139 μm-thick samples of liquid-encapsulated-Czochralski-grown n-GaAs at room temperature. A continuous broad band below 1.35 eV and a peak at 1.383 eV were observed in the amplitude spectrum. The comparison with optical absorption spectra concluded that the broad band was due to the electronic transition involving the EL2 deep-level defect. The same group used the same technique [38] and investigated PA spectra of semi-insulating (SI) and n-type GaAs at 90 K. A distinctive peak at 0.92 eV and a hump near 1.2 eV were observed for these materials. Comparison with optical and electron photoionization spectra concluded that these features were due to electron transitions involving the EL2-level defect. Quantitative spectroscopic results at the 514.5 nm line of the Ar-ion laser photoexciting Si-implanted GaAs were obtained by Zammit *et al.* [39] by fitting their gas-cell—microphonic PA frequency data in the theory by Mandelis *et al.* [33]:

Si^+ implantation dose (cm^{-2})	$\alpha_{514.5}$ (cm^{-1})
5×10^{13}	$(1.17 \pm 0.04) \times 10^5$
1×10^{14}	$(1.23 \pm 0.04) \times 10^5$
1×10^{15}	$(1.42 \pm 0.04) \times 10^5$.

Figure 8 shows the near-bandgap (1.30–1.44 eV) $\alpha(\lambda)$ spectrum of GaAs immersed in cedar oil in order to produce a high signal-to-noise ratio by use of the PDS technique [40].

The optical absorption properties of Cr-doped GaAs crystals were measured at 1200 nm using gas-cell microphonic PAS at 40 Hz [41]. The fundamental absorption edge was found to be at 870 nm. The spectral peak at 1200 nm is well-known to be due to the Cr^{2+} center. The RG model was used for the quantitative results given in terms of α(1200 nm) vs. concentration. An increasing non-linearity with increased Cr content was thus found due to the presence of several Cr states, such as neutral Cr^{3+} and doubly-ionized Cr^+ states besides the Cr^{2+} state. Wasa *et al.* [42] used a piezoelectric ZnO transducer and obtained GaAs spectra in the 0.8–1.3 eV range. The bandgap was determined to be approximately at 0.88 eV and several peaks appeared which were ascribed to light absorption by non-radiative centers within the bandgap, formed by dislocations and Cr impurities. Qualitative piezoelectric PA spectra of molecular-beam-epitaxy (MBE)-grown GaAs lay-

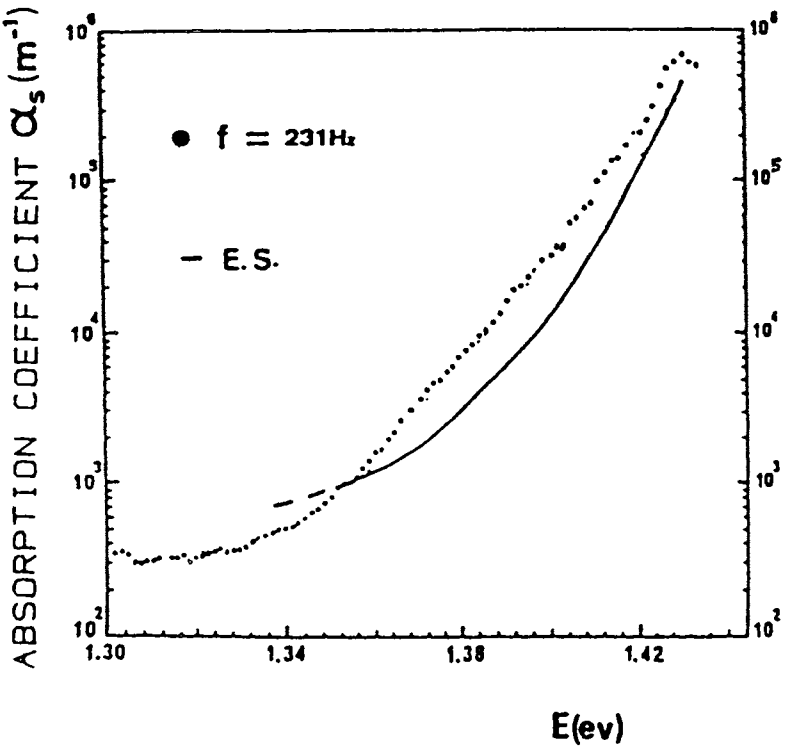

Fig. 8. Optical absorption spectrum of GaAs deduced from PDS data and compared with ellipsometry (E. S.). (From Fournier *et al.* [40] with permission from the publisher.)

ers on GaAs substrates in the photon energy range 1.1–1.5 eV and in the temperature range of 90 to 290 K were produced by Ikari *et al.* [43]. A broad (*D*) band ranging from 0.8 to 1.44 eV with a maximum near 1.3 eV, and a sharp (*Q*) peak at 1.485 eV were observed in the 90 K spectra. These features vanished under secondary illumination. The *D*-band was found to originate in electronic transitions involving EL2-level defects in the GaAs substrate. The *Q*-peak was attributed to electronic transitions from shallow acceptors such as carbon in GaAs.

GaP 8

Qualitative microphonic PA spectra in the saturation regime were obtained by Tokumoto *et al.* [21], showing abrupt changes at 540 nm, which corresponds to the fundamental absorption edge of GaP. This has led to a calculation of the indirect bandgap of GaP at 2.30 eV. For a coarse-powder sample, the indirect bandgap of GaP was measured by Rosencwaig [30] to be

approx. 2.80 eV. Pankove [44] reports 2.30 eV for the GaP bandgap. Fesquet *et al.* [45] used a method of measurement of $\alpha(\lambda)$ of thick GaP based on a simplified version of the RG model, which allowed them to deduce this parameter directly from the PA amplitude signal measurement, irrespective of the light-modulation frequency. The equation for the normalized gas-cell—microphonic PA signal (Cases 1b, 2b, and 2c of the RG model) valid for all optical-absorption-coefficient ranges becomes

$$Q = \frac{\alpha\mu}{[1 + (1 + \alpha\mu)^2]^{1/2}}. \tag{18}$$

Here, normalization is meant with respect to the maximum value Q_s of the PAS signal obtained for high values of α (PA saturation region). Application of Eq. (18) to the PA data yielded the absorption spectrum of Fig. 9. Along with the PAS-deduced spectrum Fig. 9 also shows data (solid line) obtained using ellipsometry in the range between 450 and 550 nm [46]. There is good agreement between the two sets of results in the overlap region 459 nm $\leq \lambda \leq$ 539 nm and for modulation frequencies 90 Hz $\leq f \leq$ 620 Hz. Complementary gas-cell—microphonic PA spectroscopic data were obtained from 0.2–1 mm-thick GaP crystals by Fathallah and Zouaghi [47], in the range 2.1–2.3 eV, and are shown in Fig. 10. These spectra correspond to optical absorption coefficients in the 15–200 cm^{-1} range and could not be obtained with the front-surface-illumination method. The authors used back-surface illumination with the microphone positioned to receive PA signals in the transmission mode, and used the modified RG theory relevant to this type of detection [48].

9 InSb

Tokumoto *et al.* [21] have reported a qualitative PA InSb spectrum obtained by the gas-cell—microphonic method in the PA saturation region, which correlates well with the complement of the conventional reflectance spectrum, $1\text{-}R(\lambda)$, and exhibits three minima corresponding to E_2, $E_1 + \Delta_1$ and E_1 transitions. Baltassare and Cingolani [49] obtained a reflectivity spectrum of InSb from the microphonic PA spectrum. The reflectivity was calculated from the PA signal $Q(\lambda)$ as

$$Q(\lambda)/I_0(\lambda) = 1 - R(\lambda), \tag{19}$$

where I_0 (λ) is the intensity of the incident radiation. These authors quantified the various electronic transitions in InSb at 2.42 eV (E_1'), 2.75 eV (E_1), 3.30 eV (E_2), 4.32 eV (E_3) and 4.80 eV (E_4), all corresponding with optical peaks identified by Piacentini *et al.* [50].

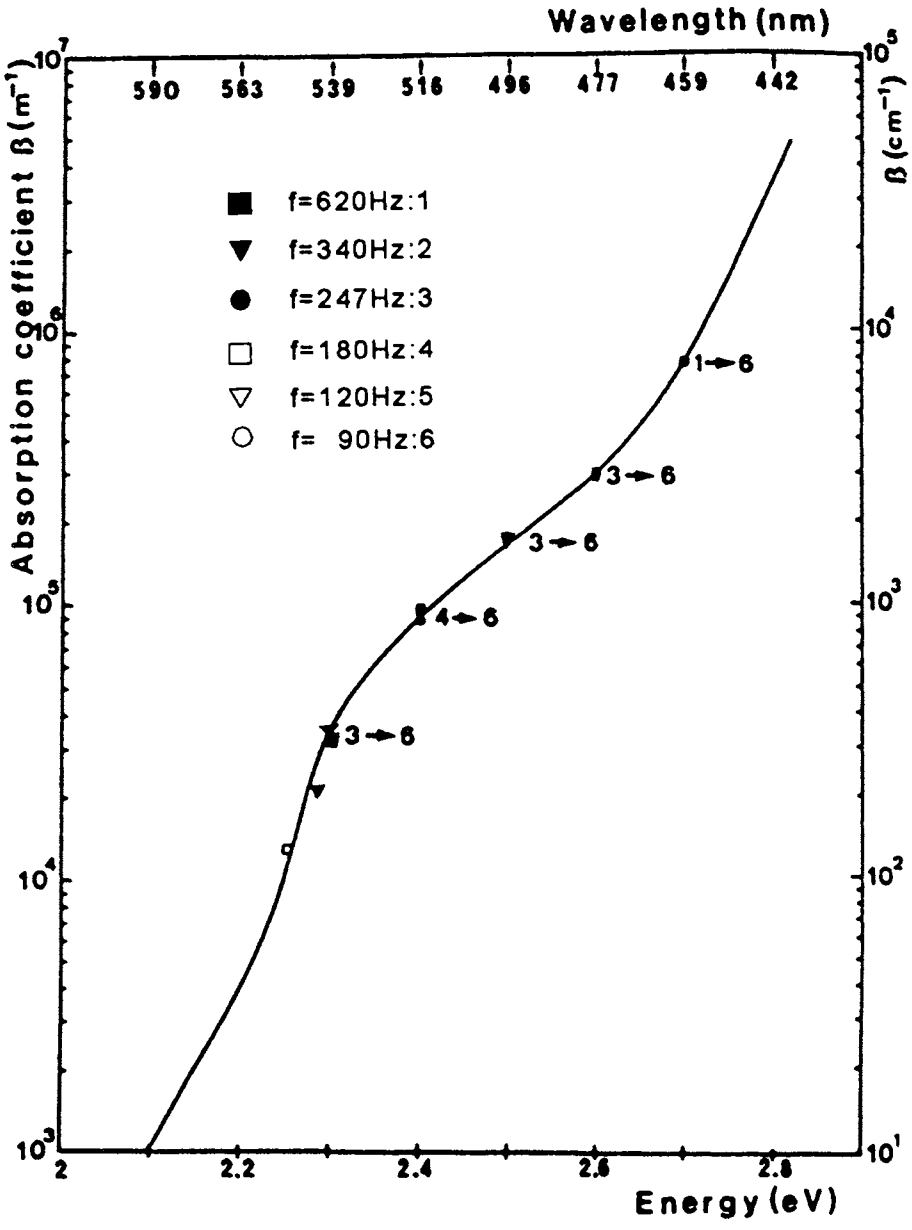

Fig. 9. Experimental results of $\alpha = \beta(\lambda)$ corresponding to various modulation frequencies (1–6) for GaP in the 2.1–2.9 eV range. The $\beta(\lambda)$ curve (solid line) was obtained from optical measurements using ellipsometry. The points on the curve correspond to two light-intensity-modulation frequencies, numbered as shown in the caption. The two unmarked, lowest-absorption-coefficient points correspond to 340 Hz (inverted triange) and 100 Hz (square). Both $\beta(\lambda)$ ordinates are PAS results: the left scale is graded in m^{-1}; the right scale is graded in cm^{-1}. (From Fesquet *et al.* [45] with permission from the publisher.)

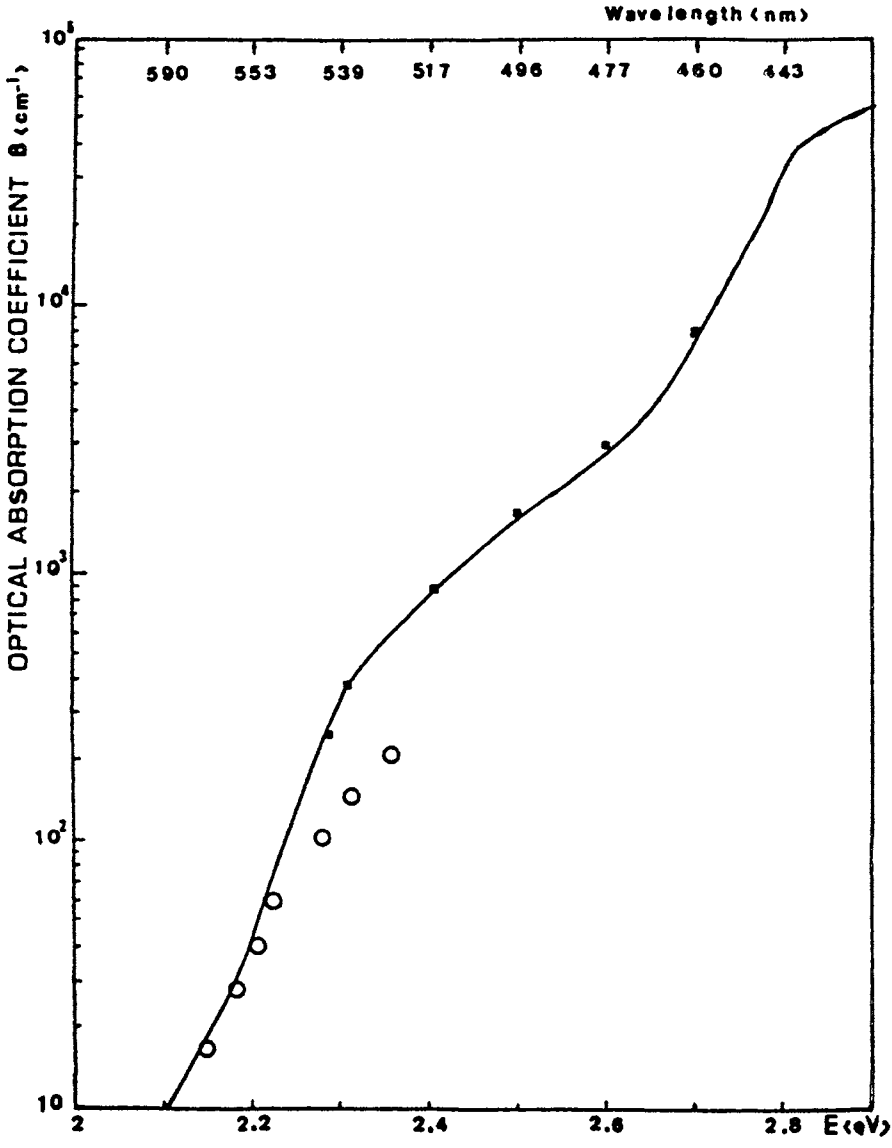

Fig. 10. Optical absorption spectrum $\alpha = \beta(\lambda)$ of GaP obtained by ellipsometry [46] (solid curve); front-side PA detection (■); and reverse-side PA detection (○). (From Fathallah and Zouaghi [47] with permission from the publisher.)

10 InP

Piezoelectric PAS with a PZT transducer was used by Yoshinaga *et al.* [51] to obtain spectra of InP in the range 400–1200 nm and various implantation fluences, including an unimplanted sample. The spectra were qualita-

tive and their shape depended on the optical reflectance as $1\text{-}R(\lambda)$ above the bandgap, where $\alpha \sim 10^4\ \text{cm}^{-1}$. The band edge yielded the PA value for the bandgap $E_G = 1.34$ eV.

GaSe 11

This material is characteristic of layered semiconductors. The gas-cell microphonic PA spectra of crystalline GaSe have been studied extensively in the neighborhood of the intrinsic absorption edge by Todorovic and Nicolic [36, 52]. The measurements were carried out at room temperature with 100 μm-thick samples. A peak appears in the PA spectrum at 2.02 eV, and the PA signal remains photon-energy independent above that peak. Comparing the results with optical absorption data, the authors concluded that the peak at 2.02 eV is due to formation of excitons. The RG theory was applied to experimental PA data with the absorption coefficient of GaAs given approximately by [52]

$$\alpha(E) = \alpha_0 \frac{\exp[\pi\sqrt{(E - E_G)/E_e}]}{2\sinh[\pi\sqrt{(E - E_G)/E_e}]}, \tag{20}$$

where E_e is the exciton binding energy, and α_0 is the absorption coefficient calculated neglecting Coulomb effects. This equation was fitted to the PA data with E_e being treated as a fitting parameter and E_G being defined by the position of the exciton peak, which is at $E_G - E_e$. The absorption profile of Fig. 11(a) was thus obtained with the following parameters:

$$\alpha_0 = 1430\ \text{cm}^{-1}; \qquad E_e = 17.5 \pm 0.5\ \text{meV}; \qquad E_G = 2.017 \pm 0.003\ \text{eV}.$$

Rochon and Racey [53] measured the optical transmission of two single-crystal GaSe specimens, and also used gas-cell microphonic PAS to measure the near-gap region photoacoustically and compare it to the optical spectrum. They observed that whereas the optical $\alpha(\lambda)$ spectra of the two samples were essentially identical around the band-gap edge, large differences appeared in the (thermally thin) PA spectra. They concluded that the PAS technique is not very appropriate for determining E_G for GaSe, but its usefulness centers around the study of near-gap phenomena, such as impurity states and the Urbach tail.

Ikari *et al.* [54] have studied the piezoelectric PA spectra of p-GaSe at 99, 113 and 295 K. The thickness of the sample was 350 μm, and a sputtered ZnO film transducer was used as the PA detector. A maximum was observed at 2.0 eV at 295 K, in good agreement with the direct-exciton formation [52]. The exciton ground-state ionization energy (Rydberg energy) was estimated to be 19.5 meV. A detailed discussion of low-temperature GaSe spectral features appears in Mandelis [2], Chapter 17, pp. 426–440.

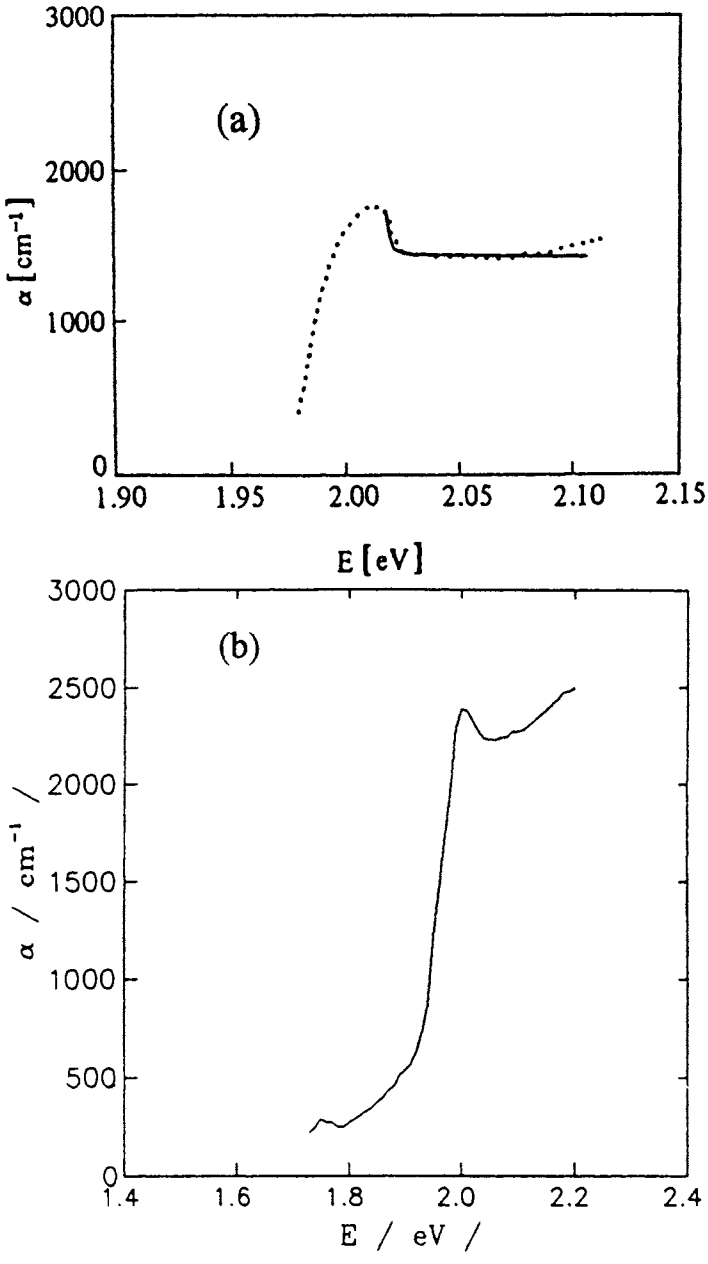

Fig. 11. a) Absorption edge of GaSe: experimental (.....) and theoretical (_____) absorption coefficients; b) Extended $\alpha(\lambda)$ spectrum of GaSe obtained from an analysis of PA amplitude and phase data. (From Todorovic and Nicolic [52] with permission from the publisher.)

CdS 12

Much PAS work has been done in measuring the band-gap energy of the direct semiconductor CdS:

E_G (eV)	T (°C)	Reference	Comments
2.4	Room	[30]	Powder
2.45	Room	[22]	Powder
2.40 ± 0.01	80	[55]	Polycrystalline films
2.35 ± 0.01	240	[55]	"
2.28 ± 0.01	300	[55]	"
2.34 ± 0.01	360	[55]	"
2.37 ± 0.01	470	[55]	"
2.38 ± 0.01	505	[55]	"

These values are to be compared to optically obtained data at room temperature: 2.42 eV [31]; and 2.48 eV [56]. Table I shows the spectral positions of seven states in CdS measured by gas-cell—microphone PAS compared to measurements made with photoconductivity and photoluminescence techniques. Table II shows the locations of the A-, B-, and C-exciton absorption in CdS measured by piezoelectric PAS in the transmission mode ("TPAS") with the transparent $LiNbO_3$ transducer contacting the back of the sample. Comparisons with optical absorption, electroreflectance, and photoconductivity measurements are also given. These tables and detailed discussions on CdS PAS can be found in Mandelis [57].

TABLE I[a]

The Values of Wavelength Corresponding to the Light Absorption Due to Seven States in CdS Measured by Various Methods (units:nm)

	Photoconductivity[b]	Photoluminescence[c]	PAS	Nature

13 CdSe

Powders of CdSe were examined using gas-cell—microphonic PAS [22]. The band gap was calculated to be $E_G = 1.88$ eV compared with 1.74 eV (optical) [31]; 1.75 eV (powder; PAS) [30]) and 1.8 eV (optical) [44].

14 CuO

Toyoda and co-workers have made extensive gas-cell—microphone PA spectroscopic measurements of Cu and its various oxides (including the semiconducting CuO) in the X-ray absorption, near-edge structure (XANES) regions using synchrotron radiation. These spectra are not directly comparable with existing data in *HOC I* or *II,* but they represent novel PAS applications in spectral regions hereto uncharted. These spectra were compared to optical-density X-ray spectroscopy in the 8.95–9.10 keV range [58]. The two sets of spectra were similar; however, the results showed that the increase and changes of the PAS-signal detailed structure at the XANES region were different from those of the X-ray absorption coefficient. Other Cu compounds studied by these authors included Cu_2O and pure Cu metal.

15 As_2S_3

Tanaka *et al.* [59] have utilized PPES in the thermally thin limit of the MZ model, with experimental data obtained using a PVDF thin-film transducer, thin-transparent CuI electrodes and an amorphous As_2S_3 film sample. The $\alpha(\lambda)$ spectrum thus obtained is shown in Fig. 12. A comparison with

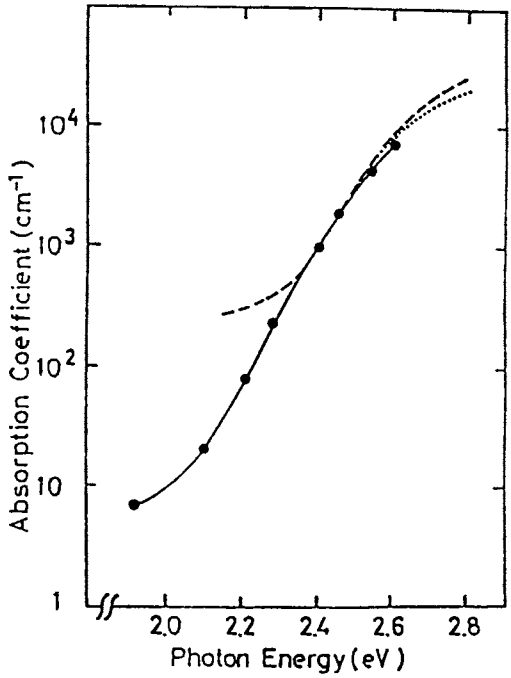

Fig. 12. Spectral dependence of the absorption coefficient of evaporated As_2S_3 films, measured with PPES (solid line). For comparison, results obtained by thermocouple photothermal spectroscopy (dashed line) and by conventional transmission spectroscopy (dotted line) are also shown. (From Mandelis [2] with permission from the publisher.)

conventional transmission spectroscopy and with thermocouple photothermal spectroscopy (PTS) is also shown in Fig. 12. It is seen that the dynamic range of PPES ($\sim$10 cm^{-1}) is superior to the conventional spectroscopies, giving reliable results down to 1.9 eV photon energy. The transmission technique yielded reproducible results for $\alpha \geq 5 \times 10^3$ cm^{-1}, and PTS had a higher dynamic range of $\alpha \geq 5 \times 10^2$ cm^{-1}. A qualitative gas-cell—microphone PA spectrum of a layered single-crystal As_2S_3 sample was also presented by Nicolic and Todorovic [36]. From the "knee" of the spectrum these authors calculated the bandgap energy $E_G = 2.65$ eV.

Tanaka *et al.* [60] employed a $LiTaO_3$ pyroelectric crystal transducer and CuI electrodes to produce the PPE absorption spectrum of the annealed amorphous semiconductor As_2S_3 shown in Fig. 13. This configuration was used instead of a PVDF transducer so as to withstand annealing temperatures of the samples at approximately 180°C. The difference in the absorption edge between the annealed and the illuminated state at 300 K corresponds to the so-called reversible photodarkening effect [60].

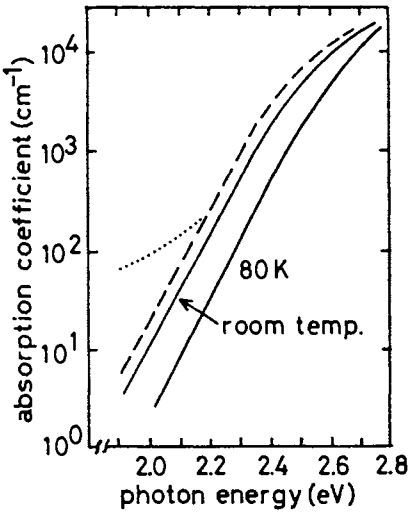

Fig. 13. The optical absorption edges of an annealed As_2S_3 film at room temperature and 80 K (solid lines). The characteristics at room temperature after illumination (dashed line) and under illumination (dotted line) are also shown. (From Tanaka *et al.* [60] with permission from the publisher.)

16 Se

Tanaka *et al.* [60] employed a 9-μm-thick PVDF film transducer to produce PPE spectra of amorphous Se. Figure 14 shows the resulting $\alpha(\hbar\omega)$ spectrum in the optical gap region, overlapping the Urbach tail represented by

$$\alpha \propto \exp(\Gamma\hbar\omega), \tag{21}$$

where Γ is the steepness parameter [61]. Figure 14 also shows the results obtained by Ceasar *et al.* [62] using the gas-cell—microphonic PAS technique. The high-energy end of the Urbach tails agree between these two sets of data, with the PPES technique exhibiting sensitivity of $\alpha L \geq 10^{-2}$. The PPE spectra in the $\leq$ 1.8 eV region deviate from the Urbach tail, because they are due to stray absorptions in the pyroelectric sensor.

Ram *et al.* [22] have measured qualitative PA spectra of powdered Se at room temperature. They found the bandgap energy to be E_G = 1.85 eV to be compared to the optical value of 1.80 eV [63].

17 $Ga_{1-x}Al_xAs$

In this case, and others involving multilayered structures, photothermal investigations have led to the determination of both the substrate *and* the film. The major rival methodology is ellipsometry, which is very convenient

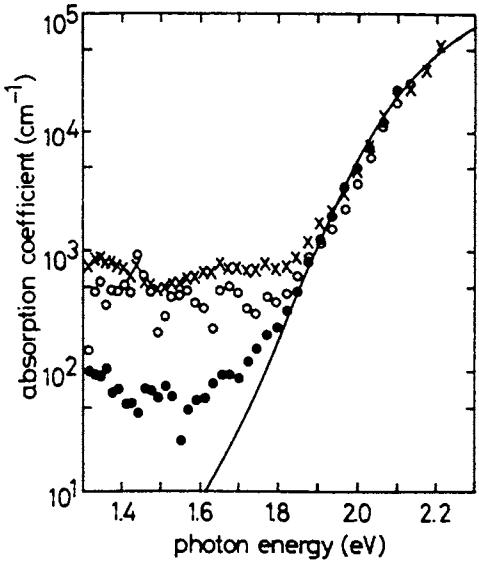

Fig. 14. The optical absorption edge of amorphous Se evaluated with PPES and from a PAS measurement (solid line). The PPES data are given for film thicknesses of 1.43 μm (•); 0.96 μm (○); and 0.74 μm (×). (From Tanaka *et al.* [60] with permission from the publisher.)

for monitoring the growth process of films, as polarized light is mainly sensitive to both the film thickness and the real part of the refractive index. Nevertheless, for low absorptions photothermal methods exhibit higher sensitivity [40]. Fournier and Boccara [40] and Yacoubi [64] utilized the two-layer theory of the PA/PT effect [33, 34] along with PDS-derived spectroscopic data from substrate GaAs to obtain the quantitative $\alpha(\lambda)$ spectrum of $Ga_{1-x}Al_xAs$ films deposited on GaAs. x is the mole-fraction of Al in the ternary GaAlAs alloy-semiconductor crystal matrix. The results are shown in Fig. 15.

Kubota *et al.* [65] measured the qualitative piezoelectric PA spectra of epitaxial layers (1.5 μm) of $Ga_{1-x}Al_xAs$ on GaAs wafers (300 μm). The incident light impinged on the epitaxial layer, and the PZT transducer was attached to the GaAs substrate. A steep rise of the PA signal at 1.42 eV due to the direct band-to-band transition of GaAs, as well as a less sharp decrease around 1.90 eV was observed. This energy is nearly equal to the indirect transition edge of $Ga_{1-x}Al_xAs$. Therefore, it was found by means of PZT PAS that $E_{G,GaAlAs}^{indirect} \approx 1.90$ eV for both $x = 0.25$ and 0.3.

a-Si 18

Quantitative $\alpha(\lambda)$ spectra of amorphous Si abound in the photothermal literature. Amer and Jackson [66] presented a detailed discussion on the appli-

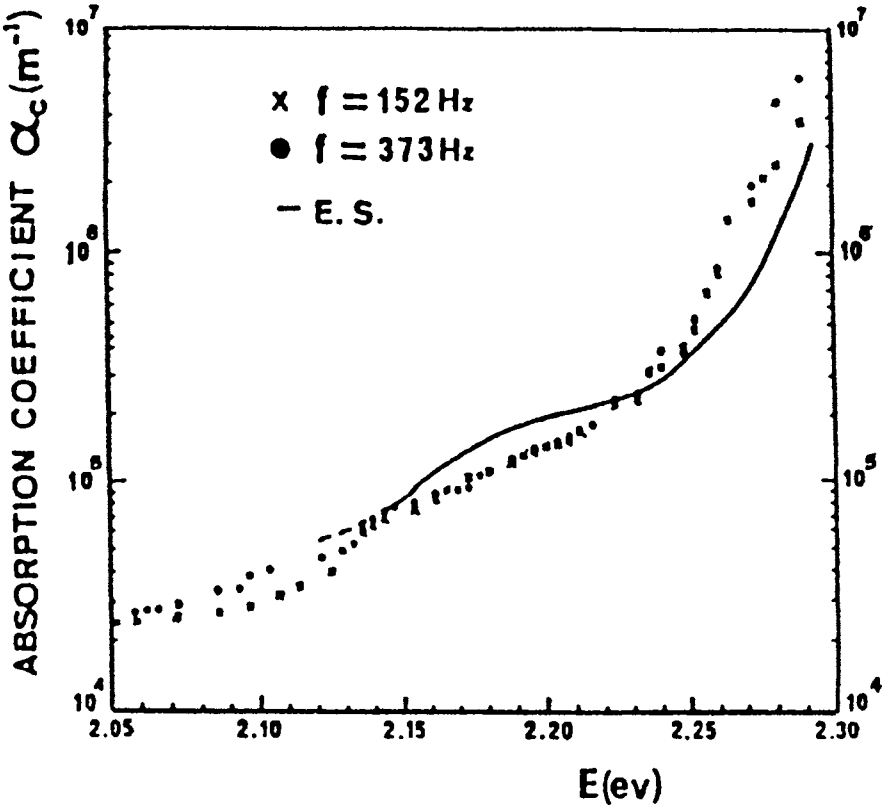

Fig. 15. Optical absorption spectrum of $Ga_{1-x}Al_xAs$ obtained using PDS data; x is the mole-fraction of Al in the ternary alloy semiconductor. The solid line is the spectrum obtained for comparison with the ellipsometric technique (E. S.). (From Fournier and Boccara [40] with permission from the publisher.)

cability of PDS to the measurement of the optical absorption coefficient of a-Si thin films under a variety of growth conditions. The advantage of photothermal techniques, such as PDS, is in the low-α region of the thin-film spectrum, where the film is entirely thermally thin and optically transparent: In this limit, the PDS signal is simply given by

$$< S(\lambda)/S_{\text{sat}} > = 1 - \exp[-\alpha_f(\lambda)\ell], \tag{22}$$

which gives the thin-film absorptance for an incoherent pump source. In Eq. (22) $< >$ denotes averaging of the interference fringes on a logarithmic scale, and S_{sat} is the saturated PDS signal obtained in the high-α region. Figures 16–20 are quantitative PDS spectra of a-Si in the 0.5 eV–2.0 eV range, measured by Amer and Jackson and their co-workers [67–70]. Figure 16 shows the effect of substrate temperature on the optical absorption spectrum: The sub-gap absorption is lowest for material deposited at 230°C and

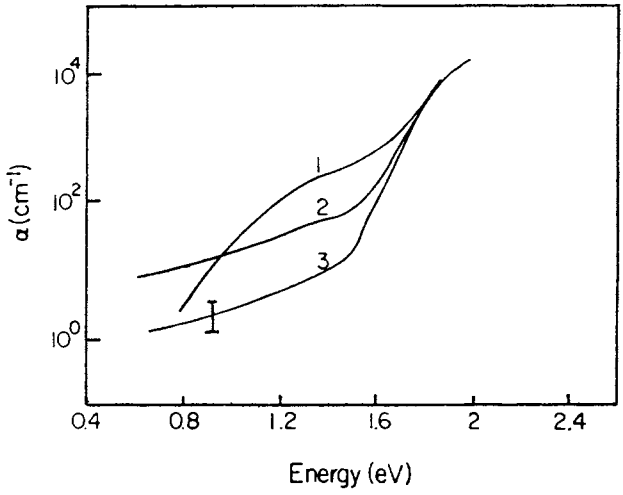

Fig. 16. The substrate temperature dependence of gap-state absorption (undoped a-Si): (1): 100°C; (2): 330°C; (3): 230°C. (From Jackson and Amer [67] with permission from the publisher.)

increases for both lower and higher deposition temperatures. The effect on $\alpha(\lambda)$ of increasing film-deposition power density on the sub-gap absorption for a constant substrate temperature is shown in Fig. 17. The shoulder which appears in the 1.25 eV range is due to large defect densities in the high-deposition power a-Si films. The effects of single doping are shown in Fig. 18. The $\alpha(\lambda)$ spectra for various phosphorus doping levels are shown in

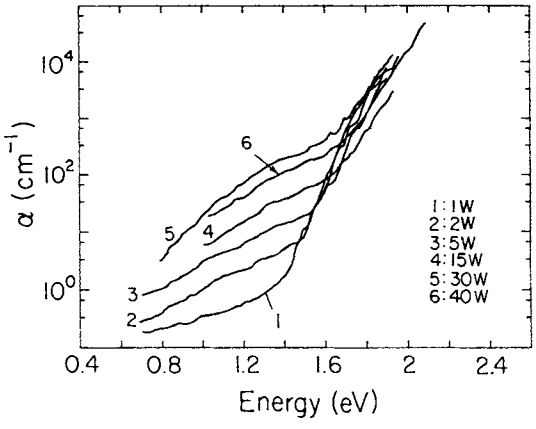

Fig. 17. The dependence of gap-state absorption on deposition power (undoped material). (1): 1 W; (2): 2 W; (3): 5 W; (4): 15 W; (5): 30 W; and (6): 40 W. (From Jackson and Amer [68] with permission from the publisher.)

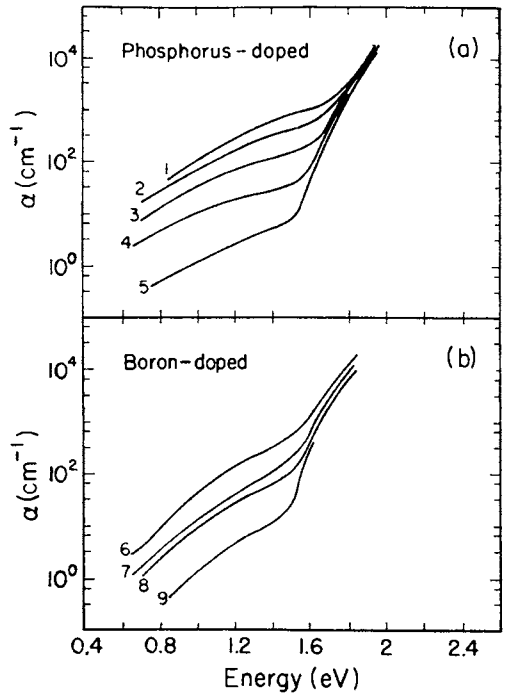

Fig. 18. The dependence of gap-state absorption on the type and level of doping. (a) PH_3 doping concentration: (1): 10^{-2}; (2): 10^{-3}; (3): 3×10^{-4}; (4): 10^{-5}; and (5): 10^{-6}. (b) B_2H_6 doping concentration: (6): 10^{-3}; (7): 3×10^{-4}; (8): 10^{-4}; and (9): 10^{-5}. All doping concentrations refer to gas-phase concentration. Substrate temperature is 230°C, and the rf deposition power is 2 W. (From Jackson and Amer [68] with permission from the publisher.)

Fig. 18a. The gap-state absorption increases and the Urbach edge broadens as the *P*-concentration is increased. Figure 18(b) shows that boron-doping has a similar qualitative effect on the absorption spectrum. The results of Figs. 16–18 demonstrate that the optical absorption coefficient of a-Si thin films is highly sensitive to doping and deposition conditions. The number of defects can be estimated by separating the sub-gap defect absorption from the exponential band-tail absorption [68]. The excess optical absorption α_{ex} due to gap-state defect absorption is given by:

$$\alpha_{ex}(E) = \alpha - \alpha_0 \exp\left(\frac{\hbar\omega}{E_0}\right), \tag{23}$$

where a_0 and E_0 are obtained from a fit to the exponential absorption. The defect number density is related to the sub-gap optical absorption by [66]:

$$N_s = 7.9 \times 10^{15} \int \alpha_{ex}(E)\, dE. \tag{24}$$

By combining Eq. (24) with the PDS results of a thickness-dependence study [69], it was found that for low-defect a-Si the film surface (or its interface with the substrate) has a defect density of $\sim 10^{22}$ cm^{-2} dangling bonds, (see Fig. 19). The absorption spectra are consistent with a defective surface layer of $\sim$ 5 nm thickness and is similar to that obtained from the highly defective bulk a-Si:H. Figure 20 shows the effect of illumination with broad-band light on the gap-state absorption of an undoped a-Si sample. The spectra show a clear and reproducible enhancement in the gap-state absorption coefficient after illumination. Annealing at 150°C in the dark restores the magnitude of $\alpha(\lambda)$ to its original value [70]. By using Eq. (24), the density and energy position of the optically induced defects can be determined.

Amato *et al.* [71] have introduced a new method for determining the surface-state absorption in a-Si thin films, based on the enhancement of the interference fringe amplitude in PDS spectra due to the presence of surface states in the region below 1.5 eV.

Ceasar *et al.* [72] have used gas-cell—microphone PAS to estimate the density of defect states responsible for the sub-gap tail of $\alpha(\lambda)$ of a-Si:H thin films prepared by ion-beam deposition. The values of α measured by PAS were found to be complimentary to those estimated by optical transmission and lay further toward the low-absorption, infrared region, down to

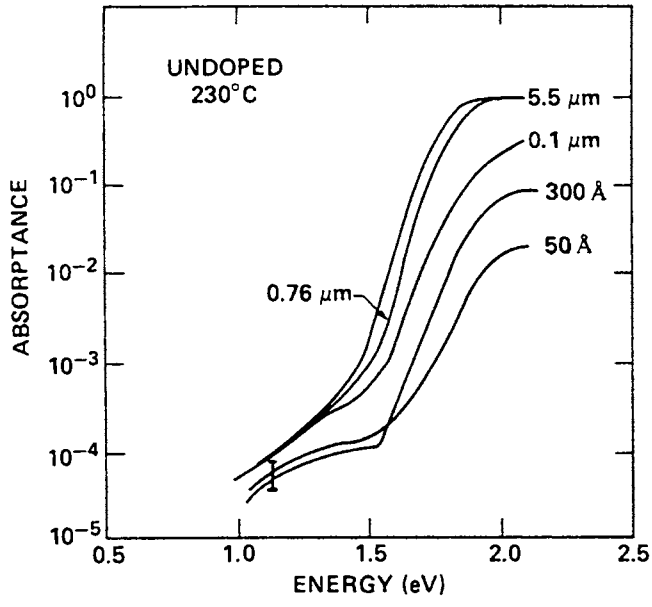

Fig. 19. Thickness dependence of the absorption coefficient in undoped a-Si at 230°C. (From Jackson *et al.* [69] with permission from the publisher.)

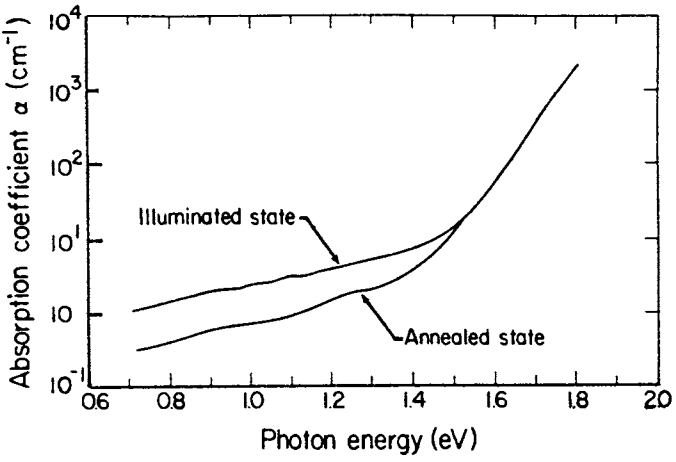

Fig. 20. The effect of illumination on the absorption spectrum of undoped a-Si:H. (From Amer *et al.* [70] with permission from the publisher.)

0.4 eV (see Fig. 21). The extension of the $\alpha(\hbar\omega)$ dynamic range to this sub-gap regime is a clear advantage of photothermal-based spectroscopies over purely optical techniques. Yamasaki [73] has also performed gas-cell—microphonic PAS studies of undoped hydrogenated a-Si as a function of the ambient temperature, the deposition temperature and the post-annealing temperature. The resulting absorption-coefficient spectra were determined between 2.0 and 0.6 eV and were of similar quality to those derived by Amer and Jackson [66]. Amato *et al.* [74] investigated the optical absorption coefficient of low-pressure, chemical-vapor-deposition (LPCVD) a-Si:H by using a combination of analytical techniques: Optical spectroscopy for the above-bandgap transitions, PAS in the sub-gap range, and the constant photocurrent method (CPM) in both regions. Differences in sensitivity to surface states and to inhomogeneities in the material along the growth axis were found. Figure 22 shows those differences between PAS and CPM spectroscopic measurements of $\alpha(\hbar\omega)$. Based on these spectra, a simple growth-kinetic model suggested that the growth kinetics could change during the film-deposition process. Ishiguro and Tokumoto [75] also reported on the improved resolution and accuracy of gas-cell—microphonic PA spectra from undoped and doped a-Si thin films over optical transmission data (see Fig. 23). The spectral photon-energy ranges were > 0.5 eV, similar to those studied by Ceasar *et al.* [72]. Tanaka [76] gives a detailed discussion on the physics behind the variations of the optical absorption coefficients of amorphous semiconductor thin-films as measured by photothermal spectroscopies.

More recently, PPES has been applied to the quantitative simultaneous measurement of two important spectroscopic parameters of amorphous Si thin-films: the optical absorption coefficient and the nonradiative quantum

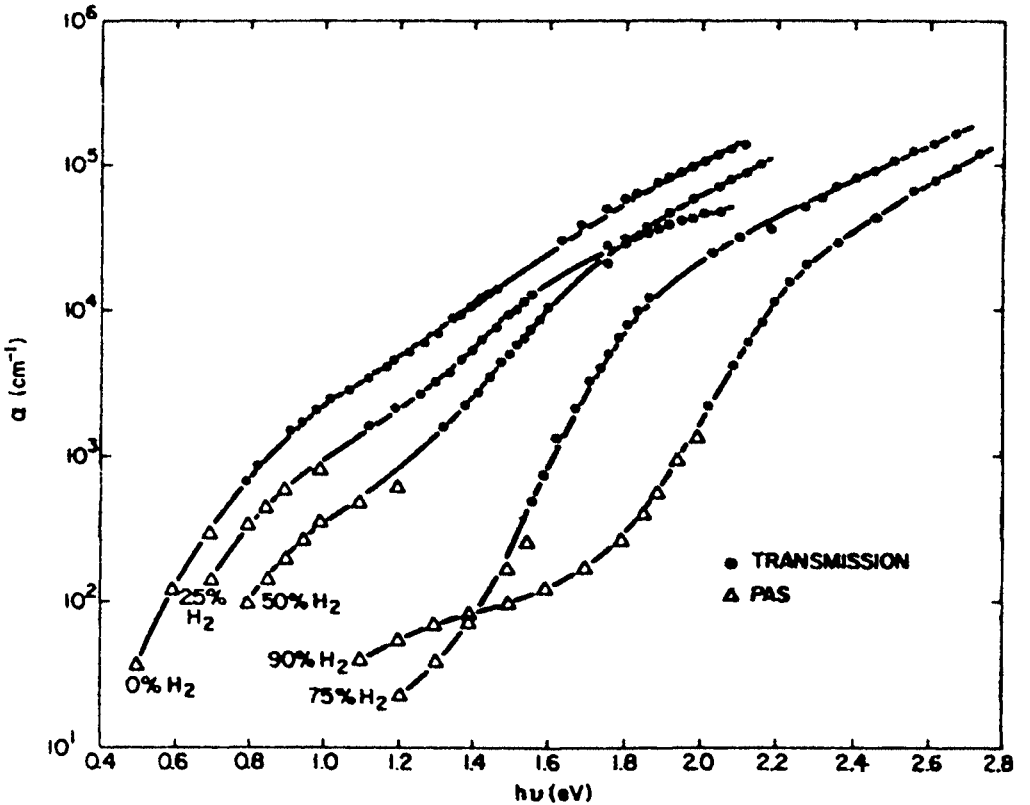

Fig. 21. Optical absorption-coefficient spectra for a-Si:H films made with ion beams of various H_2 compositions. (From Ceasar *et al.* [72] with permission from the publisher.)

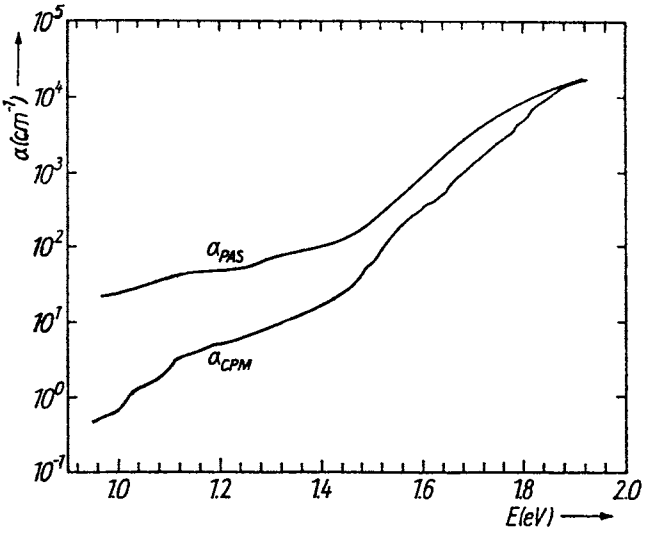

Fig. 22. Optical absorption-coefficient spectra obtained by means of PAS and CPM on a typical LPCVD a-Si:H sample. (From Amato *et al.* [74] with permission from the publisher.)

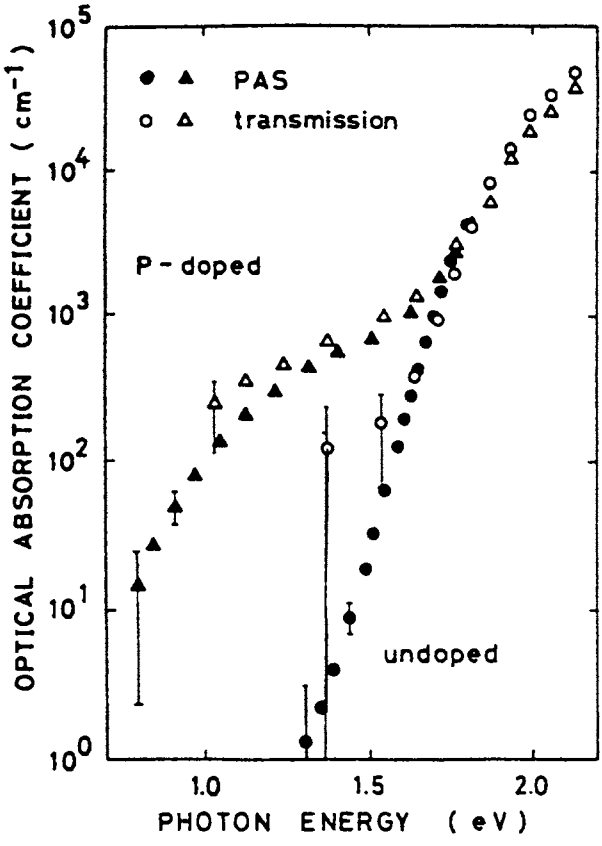

Fig. 23. Comparison of optical absorption-coefficient spectra obtained by the optical transmission method and PAS, for undoped and doped a-Si thin films. (From Ishiguro and Tokumoto [75] with permission from the publisher.)

efficiency [77]. As a back-surface (thermal-wave transmission) detection technique, PPES can be used to measure the absorption-coefficient spectrum in the thermally thick configuration of Eq. (17), whereas it can measure the optical-to-thermal energy conversion efficiency spectrum in the thermally thin configuration of Eq. (16). Based on this feature of PPES, Mandelis *et al.* [77] and Fan and Kakalios [78] obtained both spectra for a-Si:H samples for photon energies from 0.8 eV to 2.5 eV. This technique yielded a sensitivity of $\alpha\ell > 10^{-3}$, where ℓ is the thin-film thickness. This is of the same order as PDS with similar quality $\alpha(\hbar\omega)$ spectra. Unlike PDS, no coupling fluid is necessary (see Chapter 4 by Briggs in this volume), and the experimental geometry is simpler, enabling easy measurement of α as a function of temperature.

ZnO 19

Qualitative PA spectra of ZnO powders were measured by Ram *et al.* [22]. These authors reported the room-temperature bandgap energy of the powders as $E_G = 3.46$ eV, to be compared to 3.20 eV for the solid crystalline ZnO reported earlier [31] by means of optical spectroscopy. Toyoda *et al.* [79] measured the hard-X-ray spectrum of ZnO thin films in the EXAFS (extended X-ray absorption fine structure) region using synchrotron radiation (9.35–10.35 keV) and gas-cell—microphone PAS detection in the thermally thin limit (23–45 Hz). These spectra reflect the heat-production processes in radio-frequency-sputtered ZnO thin layers (~7 μm-thick), which exhibit oscillatory behavior with a peak at 9.95 keV. More work needs to be done to quantify these deep-energy-level features. The same group [80] performed photothermal studies of the optical spectral range, around the band-gap energy of ZnO thin films (2.6–3.4 eV). These spectra were obtained using a thermistor in contact with the sample (PTS). By ratioing the PTS signal to the absorptance 1-*T*-*R* (*T*: transmittance; *R*: reflectance) spectrum, Toyoda and Okonagi [80] showed that the mechanism for heat generation is different from the total rate of optical energy absorption below the fundamental absorption edge. It is this author's opinion that the interpretation of these phenomena may rest with the behavior of the nonradiative quantum-efficiency spectrum.

SnS 20

Nicolic and Todorovic [81] produced the microphonic PA spectrum of a prismatically shaped single crystal of SnS of 0.3 mm-thickness. The value of the bandgap energy was calculated from the spectrum to be $E_G \approx 1.24$ eV. A PA minimum at 0.85 μm (1.46 eV) was also observed, an ill-understood effect of the specific band structure of SnS. The fundamental direct energy gap of 1.5 eV was also measured from an abrupt drop of the PAS signal.

This feature was found to be in good agreement with a photovoltaic-effect spectrum [82].

21 InSe

This layered semiconductor belongs to the same family as GaSe; it is photosensitive, and is used for photovoltaic energy-converter device fabrication. Ikari *et al.* [83] have studied the piezoelectric PA spectra of 470-μm- and 115-μm- thick crystal of InSe extensively, both at room temperature and at 116 K, using a ZnO transducer. They discovered two peaks at 1.250 and at 1.212 eV at room temperature. The energy and the temperature variation of the 1.250 peak were well explained in terms of a free-exciton ($n = 1$) annihilation. The other peak was interpreted as a surface-state-related transition. These authors found that the optical absorption spectrum of InSe correlates well with the intensity of the PA spectrum in the near-band-gap region ($\sim$1.2 eV at room temperature), but no quantitative photoacoustic/photothermal measurement of $\alpha(\lambda)$ has been presented in the literature for InSe.

22 $GeSe_2$

This layered semiconductor can be grown in the form of a single crystal similar to GaSe and InSe. Nicolic and Todorovic [36] have estimated the bandgap energy from the gas-cell microphonic PA spectrum to be at $E_G \approx$ 2.53 eV.

ACKNOWLEDGMENTS

The author wishes to acknowledge the continuing support of the Natural Sciences and Engineering Research Council of Canada (NSERC) through multiple sustained Research Grants and an ongoing Collaborative Research Grant with Professor H. Ruda, which made partially possible his laboratories' contributions described in this chapter.

INTRODUCTION I

The optical properties of a material can be studied using photothermal techniques when the energy absorbed from incident light dissipates mainly as heat. This is the case for most materials, so that photothermal techniques are used on a variety of materials to characterize thermal, optical, and surface properties. We will focus on one such technique, *photothermal deflection* [1], as shown in Fig. 1. A transparent material absorbs some light from a tightly focused heating-beam, and dissipates this energy as heat. This creates a hot spot in the material, and a laser probe-beam is deflected by gradients in the refractive index $\partial n/\partial r$ that arise from thermal expansion around the hot spot. The experimenter measures the deflection of the probe-beam, first calibrating the deflection with a standard sample in which the absorption is known, and then moving on to unkown samples. Such a measure-

ment reveals the absorptance A of the material, which is the fraction of the power P that is travelling through the material which is absorbed,[1] and which is thus directly connected to the extinction coefficient k in the medium (see Section IID.)

We want to emphasize two features of photothermal deflection. First, it is a *localized* measurement—the effect relies on temperature *gradients* (Sec-

[1] P must take into account power lost to reflection (and scatter, if the material or its surface is highly scattering [2]), i.e., P must be given by the incident power P_i minus the reflected and scattered powers. Photothermal techniques have at best 10% accuracy and are usually (but not always) applied to transparent materials with polished surfaces. Under these conditions, the scatter and the $\approx 4\%$ reflection can be neglected, so that $P \approx P_i$, and the usual expression $A = P_a/P_i$ holds.

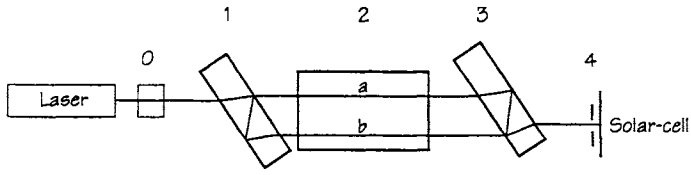

Fig. 2. An interferometer of the type used by Stone [8] to measure optical absorption in liquids.

tion IIE), and so is strongest at point sources such as the focused heating beam shown in Fig. 1. This first feature leads to two important capabilities: because the location of the region which the probe-beam senses is selected by where it crosses the heating-beam, surface and bulk absorptions can easily be separated in bulk samples (Sections IID1, IID13 give examples for bulk and film samples). For similar reasons, photothermal deflection finds widespread use as a form of microscopy, in which surface and sub-surface features of a material are found by scanning the sample and looking for changes in the deflection signal. The second feature we would like to emphasize is that photothermal deflection is *highly sensitive:* The high flux of a focused, laser heating-beam, the high sensitivity of photodiode-based beam-position sensors, and the use of a chopper to modulate the heating beam for lock-in detection combine to allow background levels equivalent to $A = 10^{-6}$ routinely [3], and $A = 10^{-9}$ more recently [4–6]. We should also mention a practical feature: the technique is simple to implement and inexpensive, if a laser source is already available with a power >100 mW.

We will finish the introduction with a few general comments about photothermal techniques, and then narrow the discussion to deflection techniques in Section II. We refer the reader to the reviews of Welsch [7] for a more detailed comparison and extensive bibliography. We divide photothermal techniques into two classes: *localized* measurements such as the deflection example just given, and *extended* measurements, typified by the interferometric measurement shown in Fig. 2 [8]. In photothermal interferometry, the experimenter places the sample in one leg of an interferometer, and detects the change in the fringe pattern that occurs when the heating beam is introduced into the sample. The difference between the classes is that the localized techniques detect the effect at a point in the sample, while the extended techniques *integrate* the thermal effect along the entire length in the material. Other examples of extended techniques include photothermal lensing (the first photothermal technique discovered) [9–11], and Fabry-Perot *etalon* work [12], as well as photoacoustic techniques, which can be adapted to both extended and localized measurements (see Chapter 3 by Mandelis, this

volume). The applications reflect the extendedness of the measurement, and include bulk optical-absorption measurements [8, 13], and trace detection of parts-per-billion impurities in bulk gases and liquids [14]. The two classes have much in common: it is the density change from heating which causes the signal, the source of the heating is usually the optical absorption from a focused heating beam, the heating beam is modulated to allow lock-in detection, and sensitivities are at least as good as $A = 10^{-6}$. In fact, photothermal techniques are the only means for detecting optical absorptions below 10^{-4} (Fig. 3); the traditional spectrophotometric approach is more appropriate for stronger absorbers because the absorption is found from the difference between large signals, the incident power minus the sum of the reflected and transmitted powers. Photothermal techniques now employ all the tools of modern optics—pulsed lasers, Fourier-transform techniques, microwave stimulation, to name a few, and have been applied to a wide range

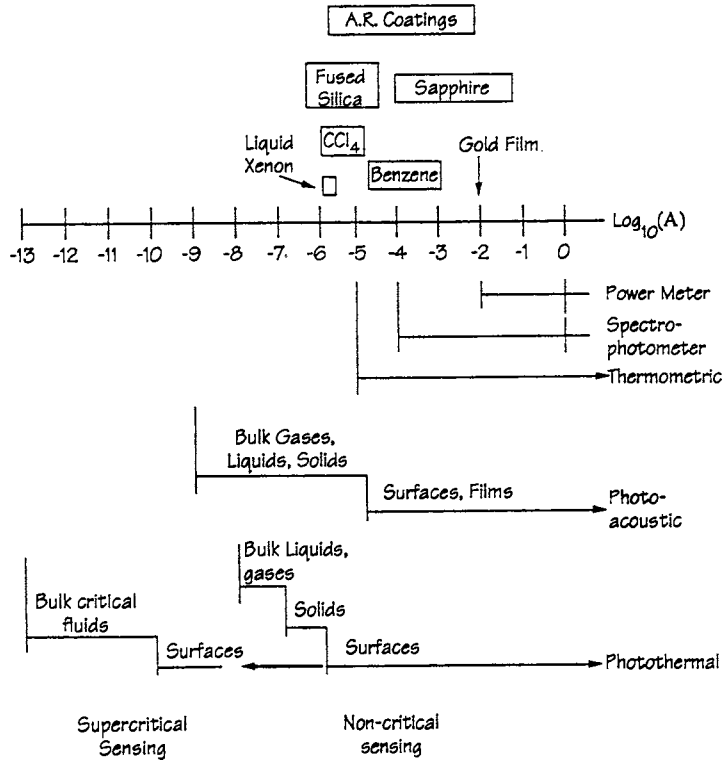

Fig. 3. A logarithmic guide to absorption measurements, giving the minimum detectable fractional absorption, $A \equiv P_{\text{absorbed}}/P_{\text{incident}}$, for various techniques, under a 1 W cw illumination. For bulk absorptions, the length l is taken to be 1 cm, where $A = \alpha l$. The arrows pointing to the right are intended to emphasize that these techniques can be used for opaque materials.

of samples for a variety of thermal, spectroscopic, and diagnostic studies. The review articles by Welsch [7], texts by Mandelis [15] and Sell [16], and others [17, 18] will quickly inform the interested reader.

PHOTOTHERMAL DEFLECTION II

Advantages and Disadvantages A

Figures 1 and 4–6 show several configurations for photothermal deflection measurements. The collinear arrangement (Figs. 1 and 6) senses the absorption at the location where the beams cross—either bulk or surface absorptions can be measured by choosing the location appropriately. In bulk measurements, the volume that contributes to the signal is set by the overlap of the heating and probe beams and the diameter of the heating beam, i.e., a cylinder $\sim$ 0.5 (mm long) $\times$ 0.05 (mm diameter). Surface measurements sense an area determined by the diameter of the heating beam, because the absorption at the surface is usually much stronger than the bulk absorption, so that the bulk can be neglected [19]. Treatments of the separation of bulk and surface contributions can be found elsewhere in [20–22], and examples in optical-constants measurements are discussed in Sections IID1 and IID13. The sensitivity for surface absorptions of solids can be increased strongly by immersing the sample in a fluid and placing the intersection of the probe and heating beams just above the surface, in the fluid. This is because the higher thermal-expansion coefficient of the fluid leads to a stronger optical effect (Section IIE.)

Though highly sensitive, the *accuracy* of this technique has been limited to the 10% level since the start of this research field. The difficulty in improving the accuracy arises because k is found from the amplitude of the deflection, which depends on quantities that are difficult to reproduce or know accurately at the site where the beams cross, principally the diameter of the heating and probe beams and the alignment between the two beams. The surface polish and sample handling must be specified for measurements of surface absorption, because the surface roughness and cleanliness strongly effect the absorption. Further, convection is an issue when working in liquids or at surfaces in air, and it is important in these types of measurements to reduce the heating power until good linearity of the signal with power is observed [6, 23]. Attempts to model these issues will be mentioned in Section II E. As a rule of thumb, only a careful calibration using known absorbers with thermophysical, geometrical, and optical properties chosen to match the unknowns will allow an accurate measurement of k. Photothermal deflection is, therefore, applied to the measurement of k in systems that de-

mand either a high sensitivity, a non-contact measurement, or a localized measurement. Photothermal deflection can also be applied to determine how much of the relaxation is thermal; transmission measurements reveal the total absorption, while photothermal techniques reveal only that portion of the absorption which relaxes thermally. For example, results from these two techniques are used by Montecchi and Masetti [24] to find the vibrational relaxation efficiency for films of gold, chromium, zinc selenide, and amorphous-carbon thin-films.

B Examples of Deflection Techniques

An example of the 10% accuracy available from deflection techniques is provided by the first exhaustive photothermal deflection study, which still serves as an instruction manual for getting started in this technique [1,3]. These authors demonstrate the accuracy of their collinear-deflection apparatus by achieving 10% agreement and repeatability between calculated and calibrated bulk-absorption measurements. They use a dye-laser heating beam to measure the spectrum of the sixth harmonic of theC—H stretching excitation of benzene at various concentrations of benzene in carbon tetrachloride from $\lambda = 580$ to 620 nm. The carbon tetrachloride serves as a non-absorbing medium in which the known amount of benzene present allows the authors to test the accuracy of the deflection measurements at various absorption levels against separate spectrophotometric measurements. In the same paper, the authors report a similar level of success for measurements of the surface-absorption spectra of In and CdS *films* on glass substrates, again calibrating the absorption in separate spectrophotometric measurements.

The "mirage" configuration shown in Fig. 4 allows the experimenter to work on opaque samples, and simplifies the process of scanning the sample [3]. Here the deflection arises from thermal expansion in the gas above the hot spot created by the absorption of the heating beam at the surface of the material. Changing the frequency and noting the phase shift in the response allows an analysis of the depth of the absorption. Alternatively, the probe beam can travel through the substrate, sensing the mirage effect from the (weaker) thermal expansion of the substrate material under the surface absorption [25]. This would be useful for detecting the absorption in processes for which the region above the surface is not optically good, such as laser ablation.

Although Murphy and Aamodt [23] find 10% accuracy and agreement with theory for mirage measurements on an electrically heated surface, in the more common case of heating from optical absorption, the agreement between the mirage measurements and theory is not as good [25, 26]. This presumably is because of the more complex geometry and alignment requirements. The convenience of the technique for imaging problems makes this an important

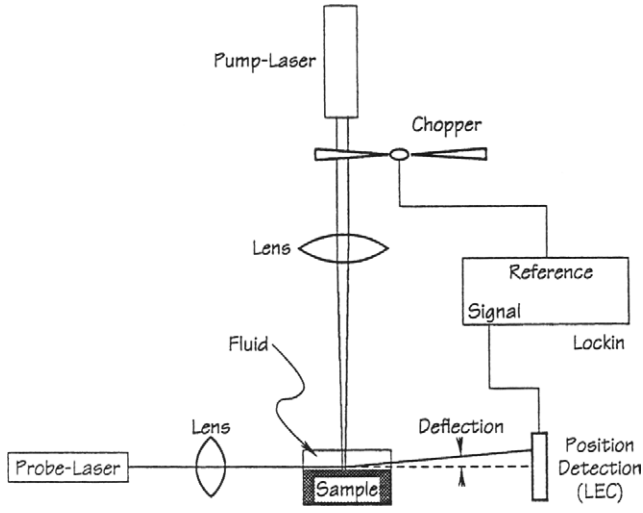

Fig. 4. A mirage photothermal-deflection apparatus using the refractive-index distortions created in the fluid or gas above the region of the absorption as a measure of the absorption.

technique, but until the mechanisms of the measurement are understood well enough to allow the measured amplitude to agree with theory, the transfer of absolute absorption levels from calibration samples to unknowns will have a larger margin of doubt than other photothermal techniques.

The remaining deflection techniques fall under the title *photothermal surface-deformation,* an example of which is shown in Fig. 5. These techniques offer advantages in imaging applications similar to the mirage technique, and in addition contain information about the thermal-expansion properties of the material itself (rather than the gas above the material.) Examples of these configurations of photothermal apparatus are available elsewhere [23, 27, 28]. A further advantage is that the surface-deformation approach gives agreement with theory closer to 10% [28, 29], presumably because the optical alignment is less demanding than for the mirage technique. Because the signal depends on the coefficient of thermal expansion of the material, surface-deflection techniques are typically used on metal films; it would be less appropriate on the low-thermal-expansion optical glasses, where one would turn to the collinear or mirage approach.

Summary of Strengths and Weaknesses C

Strengths of the deflection techniques thus generally include: 1) a combination of simplicity and very high sensitivity, 2) non-contact *in-situ* measurements, 3) adaptable to transparent, turbid or opaque samples, 4) either

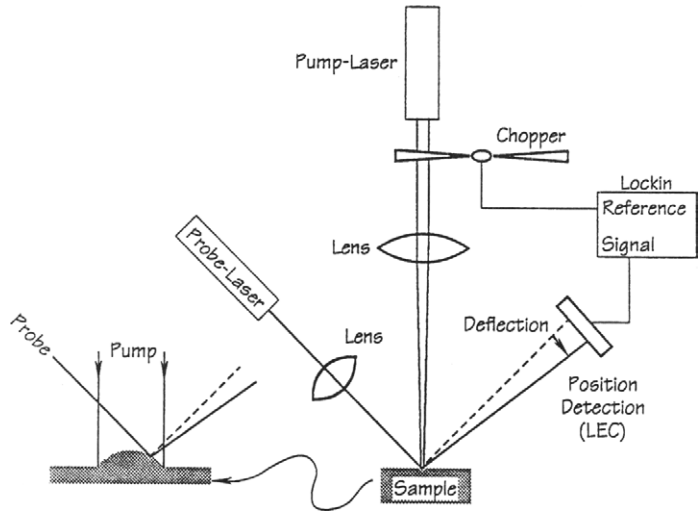

Fig. 5. A reflective photothermal deflection apparatus using the thermal expansion of the sample surface at the site of the absorption as a convex mirror, to change the angle of reflection in proportion to the absorption.

strongly absorbing or weakly absorbing and any phase (gas, liquid, solid), 5) either surface or bulk, spatial resolution to a few μm's, and 6) ability to measure dynamic processes. We should also mention that the technique has been used at cryogenic temperatures (see Section IID13). Weaknesses of the technique generally include: 1) necessity for careful optical alignment, 2) accuracy is not high, 3) modeling of 3-D heat flow is needed to understand full dynamic range, 4) provides only local measurements, and 5) requires laser with power $\gtrsim$ 100 mW. Because *deflection* measurements are localized, the measurement of k in bulk materials is probably better done using one of the *extended* techniques mentioned in the introduction—unless the surface absorption needs to be removed from the measurement. The dominant applications for *deflection* techniques today are the microscopy and characterization of surfaces, which will be evident from the following discussion. However, anyone using a single number for the absorption in a material must consider the possible effects of local variations if their application pushes the performance or depends critically on the performance of the material. The absorptance can vary locally by a factor of 100 around a surface, and 10 in bulk materials.

D Measurements of *k* Using Photothermal Deflection

The photothermal techniques yield the absorptance $A \equiv P_a/P$, where P_a is the power absorbed from a heating beam of power P in the material (see the

footnote in the introduction). In order to find the imaginary part of the refractive index, k, we first find from the absorptance A the absorption coefficient $\alpha(\text{cm}^{-1})$, which describes the spatial rate at which optical energy is converted into thermal energy, and then use $\alpha = 4\pi k/\lambda$. For example, in the simplest case of normal incidence on a semi-infinite material we have

$$A \equiv P_a/P_i = 1 - e^{-\alpha z}, \tag{1}$$

where z is the path length travelled in the absorbing material, and P_i is the power transmitted into the sample through the interface. Finding α from A can be a challenging problem: for the case of intereference coatings, Eq. (1) must take into account the multiple reflections of the heating beam within the coating, which requires careful calculation of the path length and interference effects [19, 30].

A detailed schematic of a collinear apparatus we used for precise measurement of optical absorptions is shown in Fig. 6. We include this to provide as detailed an example of an experimental set-up as we can. This is an implementation of the apparatus described by Jackson *et al.* [3], which still serves as an excellent cookbook for setting up such an apparatus, as well as for an introduction to the theory. Along with this, we recommend papers by Commandré et al. [19], Bennet *et al.* [26], Commandré and Pelletier [30] as examples of how to make a thorough study of the optical properties of a material using photothermal deflection (See Section IID14).

We now discuss materials for which k has been measured using photothermal deflection techniques. In all cases, the process involves an initial calibration using a known absorber with similar optical properties, such as the substrate thermophysical properties and film multilayer structure, in the case of thin films. We will attempt to present the strength and weakness of the individual measurements, bearing in mind that often the primary goal of the authors was to diagnose the presence of impurities or defects, rather than to produce absolute measurements of optical constants.

Aluminum Oxide and Fused Silica Glasses (Al_2O_3, SiO_2 Glasses) 1

Fused silica provides an excellent example of the role photothermal deflection can play in the measurement of optical properties: the absorption of this material is sufficiently low that it had not been measured yet [31]. The collinear-deflection technique has since been used to measure $\alpha \approx 10^{-6}$ cm^{-1} at 514.5 and 632.8 nm for synthetic fused silica, and $16\text{–}600 \times 10^{-6}$ cm^{-1} for natural fused silica [19, 32]. This gives an extinction coefficient for synthetic fused-silica of $k = 3 \times 10^{-12}$. The reason for using the deflection technique rather than an extended technique is that by crossing the beams in the bulk of the sample, the workers were able to avoid surface absorption effects which might dominate the bulk absorption. The loss in intensity due to reflections and scatter in these materials is small enough that workers take

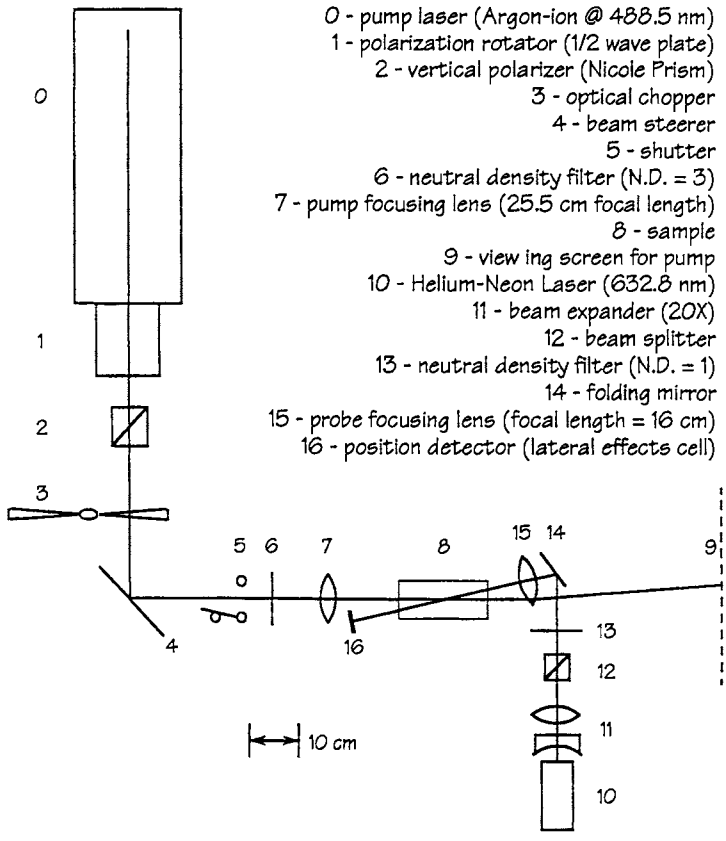

Fig. 6. A scale drawing of a typical photothermal deflection apparatus that allows a convenient variation of the power through rotation of the polarization of the Ar^+ output beam, and is characterized by a 20 μm radius probe beam and 50 μm radius heating beam at the sample location.

the intensity in the bulk to be equal to the intensity incident on the surface. Other techniques are generally forced to include the surface absorption with the bulk, and the surface absorption will usually be much stronger. We have not found bulk measurements using deflection techniques for sapphire. Our own work on surface absorptions in these materials reveals a wide range of absorptances, $10^{-5}-10^{-3}$ at 632.8 nm, depending on surface polish and cleaning [6] (recall that surface measurements can only report the fraction of light absorbed, not α). A good collection of different treatments of the problem of surface absorption in optical materials can be found elsewhere [18]. Several papers in the section on absorption losses in this reference show that surface absorptances in fused silica can be as low as $A = 10^{-6}$. Our own best fused-silica surfaces, which were superpolished by the same com-

pany that supplied some of the 10^{-6} surfaces reported in this collection, showed levels of 10^{-5}. This suggests the presence of a low-level contaminant on the surface, despite our use of modern UHV procedures to prepare the perfect sample. Workers in supercritical fluids should take note of this observation.

Amorphous Carbon Films (a-C:H) 2

Photothermal deflection was chosen for its sensitivity in recent work mapping the effects of hydrogenation on the optical absorption in amorphous-carbon films [33]. Results are given for α, which we convert to an approximate value of k using $k = \lambda\alpha/4\pi$. For example, at $\lambda = 0.6328$ μm, this gives $k = 2 \times 10^{-3}$ at an atomic fraction of hydrogen in the film of $X_H = 0.44$. This should be compared to the values $k = 0.217, 0.0348$ from transmission measurements, as tabulated by Piller [34], for which X_H was not quoted. A careful study of the absorption in a-C:H must include careful treatment of X_H, as in Compagnini *et al.* [33].

Copper (Cu) 3

The absorption spectrum of copper for $500\text{nm} < \lambda < 700\text{nm}$ is given by Spear and Russo [25] for a 0.2 μm-thick layer sputtered onto acrylic. This is a demonstration of the mirage technique performed in the substrate, and not an optical-properties paper, so the level is equivilant to the calibration from reflectance measurements, and no value for α is given. The experimental deflection is an order of magnitude lower than expected from theory, which seems to be a typical problem for the mirage approach, making it less desirable for the measurement of optical constants.

Gallium Arsenide and Amorphous Gallium Arsenide (GaAs, a-GaAs:H) 4

The absorption of 1 μm thick MBE layers of GaAs has been reported between 0.8 and 2 μm as a function of temperature of the substrate during growth [35]. The photothermal deflection technique was chosen for its sensitivity; these results fall into an area of low extinction coefficient in the subgap region not previously measured [31]. Subgap absorption-levels vary strongly with substrate growth temperature, $\alpha \approx 10^1$–10^3cm^{-1} as λ goes from 2 to 0.8μm. These results are used by the authors to determine defect-density behavior. Unhydrogenated amorphous GaAs layers show 100× higher absorption than the crystalline films and a shift to lower energies [36], similar to behavior observed for GaP (next section) and Se (Section IID7).

The hydrogenated amorphous film showed similar behavior to the crystalline film, however.

5 Gallium Phosphide (GaP)

The effect of substrate temperature during sputtering of amorphous GaP films appears to have only a slight effect on the optical absorption in the subgap region [37], in contrast to the behavior reported for GaAs (Section IID4). A smoothing of the exponential absorption edge is observed by these authors, similar to that found for amorphous Se (Section IID7), as well as a shift by a factor of 3 to lower energy compared to the absorption edge in crystalline GaP. The observed α ranges from 0.1 to 10^5 cm^{-1} as the wavelength decreases from 0.5 to 2.5 μm. Much of this region had not been explored before [38].

6 Amorphous Hydrogenated Germanium (a-Ge:H)

The amorphous thin-films of germanium and silicon (Section IID13) have been extensively studied with photothermal deflection, because the sensitivity allows the measurement of the absorption in the sub-gap region up into the more highly absorptive region where classical approaches work. For example, the region from 0.5 to 1.5 eV has been measured in a-Ge:H using photothermal deflection [39], showing the change from $\alpha = 10$ cm^{-1} at the flat absorption below the gap rising up to 10^5 cm^{-1} at the gap. Generally, these studies map the absorption as a function of the degree of hydrogenation and the defect density.

7 Amorphous GeSe and Selenium Films (a-GeSe, a-Se)

Annealing effects on 1–1.5 μm-thick GeSe films have been reported by Theye *et al.* [40], in which the authors use photothermal deflection in the subgap region. The resulting absorption ranges from $\alpha = 10^1$ to 10^3 cm^{-1} as λ goes from 1.2 to 0.5 μm. The authors find strongly reduced absorption with annealing over most of the range, but find an indication of *increased* absorption for the annealed sample at the lowest energy. Theye and co-workers later study absorption versus concentration of Se from 0 to 100% [41], over a broader range of wavelengths than their first study. The material shows a gradually increasing absorption with energy, $\alpha = 3$ to 10^5 cm^{-1} as the wavelength changes from $\lambda = 2.5$ to 0.5 μm. They note that the amorphous selenium films lack the sharp exponential absorption edge found in bulk Se.

Gold Films (Au) 8

Gold has been measured using photothermal deflection in demonstration measurements for a new surface-deformation technique [28]. The authors show the equivalence between the absorption measured on gold films using photothermal deflection with that measured using the reflectance, and demonstrate agreement between the expected and measured signal levels. The absorption coefficient they measure is $\alpha = 7.6 \times 10^5\ \text{cm}^{-1}$ at $\lambda = 0.488\ \mu\text{m}$, which gives $k = \lambda\alpha/4\pi = 2.4$, compared to $k \approx 1.8$ in Lynch and Hunter [42]. The difference is presumably due to differences in the deposition and surface finish of the film, and reinforces our point that reports of surface absorptions must include a careful specification of the surface condition at the time of measurement.

Indium Phosphide (InP) 9

Polished wafers of InP were tested by Horita *et al.* [43] for demonstrating a double-pass method to enhance the sensitivity of mirage detection. In addition, these workers used the high sensitivity to extend the measurements of k reported by Glembocki and Piller [44] to wavelengths between 1 and 1.2 μm, where the absorption had been too low to measure previously. The new results map smoothly onto the old ones, and dip down to $\alpha = 2 \times 10^{-2}\ \text{cm}^{-1}$ at 1.2 μm. As usual for the mirage technique, the calibration cannot be calculated correctly from theory. However, there is good overlap with the data of Glembocki and Piller [44], which is taken as the calibration. This is appropriate for their demonstration work, but leaves open the possibility of an offset (due, for example, to surface roughness) between the actual and reported absorption of the sample. We just want to emphasize the importance of an independent calibration and agreement with theoretical signal-levels in measurements of optical constants. The absorption of this material was also measured using photothermal deflection [45], as part of a study of the utility of photothermal deflection in the characterization of quantum wells. The authors report that they are successful in determining the absolute absorption of the quantum wells, and in addition report the absorption spectrum for the InP substrate from $\lambda = 1$ down to 2 μm, extending the work of Horita *et al.* [43] further into the relatively flat absorption region ($k \approx 10^{-2}$) below the gap at 1.3 eV.

Iron Disilicide ($FeSi_2$) 10

k and α are reported in Dimitriadis *et al.* [46] using photothermal deflection in conjunction with spectroscopic ellipsometry and X-ray diffraction in

a thorough study of this material between $\lambda = 0.5$ and 2.5 μm. Photothermal deflection was chosen for its sensitivity. The resulting k is found to grow from 1 to 3 with energy in this range, for both bulk and thin-film samples. The results establish a band gap at 0.8 μm.

11 *Lead Lanthanum Zirconate Titanate Ceramics (PLZT)*

The subgap absorption in this material has been measured in a study of the absorption centers and the effects of illumination [47]. The authors find a smooth increase in the absorption coefficient from 10^{-2} to 10^{2} cm^{-1}, for incident light between 1 and 3.5 eV. In the method of calibration, the authors show an appreciation for the need to duplicate the thermal properties of the unkown materials: they paint the surface of an identical sample with black paint to increase the absorption sufficiently to allow a cross-calibration with transmission. This still leaves serious doubt, however, in that the thermal impedance at the boundary between the paint and the sample will be very different from that of the surface absorption to the bulk in the unpainted material.

12 *Silicon (Si)*

The same work we discussed in the Section IID9 also reported measurements of α for a polished silicon wafer. Again, the results dip down smoothly from the literature values used for calibration [48], and end with $\alpha = 10^{-2}$, cm^{-1} at 1.2 μm, similar to InP. This small region is interesting because previous measurements had stopped at 1.1 μm [48], and Horita *et al.* [43] show that the absorption continues to plummet, dropping two more decades between 1.1 and 1.2 μm. Because work by Edwards [48] is used for calibration, the results of Horita *et al.* [43] are locked into consistency with the earlier work. A calibration offset may exist for this mirage work, as discussed in Section IID9.

13 *Amorphous Silicon and Hydrogenated Silicon (a-Si, a-Si:H)*

The absorptions of a-Si and a-Si:H thin films have now been measured using all of the techniques that we have mentioned. This work provides another example of the interplay between these techniques: The transmission work cited by Piller [34] lacks the sensitivity to measure the absorption in the sub-gap region of the thin film. Since then, photothermal (and other) techniques have measured the absorption in this region, revealing a wide variety of levels associated with different levels of hydrogenation (X_H) and

sample purity [49]. The surface absorption is distinguished from the film interior absorption by Umezu *et al.* [50] by studying the absorption versus the thickness of the film from 0.02 to 5 μm. The work is carried out at wavelengths starting in the supgap region and extending up over the band-edge, from 0.6 to 1.2 μm, for the purpose of exploring the nature of the surface states; α is not given. The difficulty in reaching conclusions about the absolute absorption α arises from the interpretation of interference effects, as we discussed in our general review of the technique. A treatment of this effect for amorphous silicon films can be found elsewhere [51]. These authors apply a thin-film optical analysis to extract α for 0.3 μm-thick films of a-Si:H between $\lambda = 0.6$ and 1.2 μm. They find α increasing from 10^1 to 10^4 cm^{-1} with energy in this region, with the gap edge at 0.8 μm. They attempt to resolve surface and bulk levels by fitting, to obtain the surface density of states and how these depend on light soaking and thermal annealing. A more thorough discussion of the application of thin-film optical analyis can be found in the work on TiO_2 discussed in the next section. A review of earlier work using photothermal deflection on a-Si can be found elsewhere [52]. Finally, we note that this material was studied at liquid-nitrogen temperatures, with α decreasing smoothly from 10^5 to 10^2 cm^{-1} between $\lambda = 0.5$ and 1.2 μm [53].

Titanium Dioxide Films (TiO_2) **14**

Photothermal techniques are critical for measuring k in TiO_2 (and other transparent films) where the extinction coefficient is so small in the entire visible region that it was previously inaccessible [31]. The optical properties of this material have been thoroughly measured in the literature using photothermal deflection [19, 26, 30]. This work gives $k = 1 \times 10^{-5}$–5×10^{-4}, depending principally on the sample roughness and preparation method, and independent of wavelength in the visible range where these studies were done. Note that the crossover from this flat region to the strong wavelength dependence evident in Ribarsky [54] for $\lambda < 0.4$ μm and $\lambda > 10$ μm has not been explored to our knowledge. The value of k reported at these wavelengths is $k \approx .05$, rising quickly to $k \approx 2$ [54]. This is one of the most studied materials, and one can go to the above references to find work on the effects of multilayer interference, and comparison with the more traditional techniques.

Zinc Sulfide (ZnS) **15**

A single layer of ZnS was used as a calibration signal by Commandré *et al.* [19]. In order to extract an extinction coefficient from their data, we cal-

culate k from the formula and parameters given by Commandré *et al.* [19] that take into account interference effects, with $n_1 = 2.4$ at $\lambda = 610$ nm [55]. This gives $k = 7 \times 10^{-4}$, somewhat higher than the value for cubic ZnS given by Palik and Addamiano [55], but not inconsistent with variations noted for surface absorptions in general. See references in Palik and Addamiano [55].

E Working Equations

Here we give the working equations for the simplest deflection measurement, a collinear deflection apparatus making bulk measurements. Our intention is to show, in general, how the different materials' properties affect the signal. The absolute calculation for a particular experiment must take into account any peculiarities of the new experiment and be verified against calibration standards. If such a comparison is unsuccessful, then the confidence in using the calibration standards to judge the absolute absorption of an unknown is diminished. Several workers have reported good success with models, treating the heat flow in the proper number of dimensions and taking into account the presence of surfaces [3, 6, 56–58].

When a material is heated, thermal expansion causes the density of the material to decrease, and this lowers the refractive index of the material—the speed of light increases as the density goes down. The optical effect of the change in density dominates the change in polarizability. This phenomenon is well described by a dipole approximation described by the Clausius-Mossotti equation [59], and if one takes the derivative of this equation with respect to density ρ, one finds a simple expression for the temperature derivative of the refractive index, dn/dT,

$$\frac{dn}{dT} = \frac{\partial n}{\partial \rho}\frac{\partial p}{\partial T} = -\frac{(n^2 - 1)(n^2 + 2)}{6n}\beta_p, \tag{2}$$

where we have substituted the thermal expansion coefficient at constant pressure β_p,

$$\beta_p \equiv -(1/\rho)(\partial \rho/\partial T)_p. \tag{3}$$

The signal turns out to be proportional to this term, so that the coefficient of thermal expansion plays a crucial role in the signal level: the sensitivity of the mirage approach is due to the thermal expansion in the gas above the heated surface, the use of sensing fluids in collinear measurements on solids is due to the 100× larger thermal expansion in liquids compared to solids, and the enhancement to the signal provided by supercritical fluids arises because the thermal-expansion coefficient diverges with proximity to the criti-

cal point [4, 6]. The coefficient of thermal expansion of liquids is β_p (liquid) $\approx 10^{-3}$ (K^{-1}), while for fused silica, β_p has the very low value 1.6×10^{-6} (K^{-1}). The strength of the thermal effect on n, therefore, varies from $dn/dT \approx 5 \times 10^{-4}$ or 0.03%, down to 7×10^{-7} or 5×10^{-5}% (K^{-1}). These are small effects, but they are entirely due to the process of interest, unlike the transmission approach, which deduces the absorption from the small amount of light lost from the incident beam.

The deflections are small enough that we can assume that a beam travelling in some direction z will always be deflected by gradients perpendicular to z, $\partial n/\partial r$, according to the simple expression

$$d\theta = \frac{1}{n}\frac{\partial n}{\partial r}dz, \tag{4}$$

where $d\theta$ is the angular deviation from the z-axis. This can be seen directly by considering the change in the velocity along the wavefront of a plane-wave travelling in a medium with a gradient in the refractive index along the wavefront [59]. We express this gradient in terms of the temperature gradient from which it arises, $\partial n/\partial r = (dn/dT)\partial T/\partial r$, and integrate this along the path of the probe-beam through the heated region of the sample. Assume this heated region arises from the absorption coefficient α (cm^{-1}) of a heating beam of power P, focused to a Gaussian waist-radius w_0 and chopped at a frequency ω. We take the heating and probe-beams to overlap at an angle ϕ, which gives an effective overlap length l of $l = 2w_0/\sin\phi$. If the frequency is low enough that a steady state is reached during each shutter opening, the effect will be limited by the thermal conductivity Λ of the sample, so that the final expression for the root-mean-square angular variation of the probe beam is:

$$\theta_{rms} = \frac{\beta_p}{\Lambda}\rho\frac{\partial n}{\partial \rho}\frac{\alpha l P}{\sqrt{2}\pi^2 w_0}\left[\frac{1 - e^{-2r^2/\omega_0^2}}{r/w_0}\right], \tag{5}$$

where we have assumed that the materials are transparent, i.e., that the power in the heating beam is not significantly diminished by the absorption before and while overlapping with the probe beam. If on the other hand, the frequency is high enough that the temperature is increasing at its maximum rate throughout the time the shutter is open, the signal is limited by the heat capacity of the sample c_p, and obeys

$$\theta_{rms} = \frac{\beta_p}{\omega\rho c_p}\rho\frac{\partial n}{\partial \rho}\frac{16\alpha l P}{\sqrt{2}\pi^2 w_0^3}\left[\frac{r}{w_0}e^{-2r^2/w_0^2}\right]. \tag{6}$$

The intermediate frequencies are described by integral equations that must be solved numerically [3, 6, 15, 16, 60].

The qualitative behavior common to both the low- and high-frequency forms is then a signal which is proportional to the illuminating power P and the absorption αl or A. The low-frequency signal level rolls-off to frequency-limited behavior at a frequency $f_r \equiv 4D/(\pi w_0^2)$, where D is the thermal diffusivity of the fluid, and w_0 is the waist radius of the heating beam. Low-frequency signals will be independent of frequency, and proportional to the ratio of the thermal-expansion coefficient β_p to the thermal conductivity Λ. The maximum signal will be found with the probe at $r = 0.8w_0$ from the axis of the heating beam. High-frequency signals fall off with frequency like $1/f$, and are proportional to the ratio of β_p to the constant-pressure heat capacity c_p. The probe position at maximum signal will move in, to a separation $r = w_0/2$ from the heating beam.

We repeat that the above calculations describe the signal in a collinear photothermal deflection experiment measuring the bulk absorption of a transparent material. We wanted to illustrate how the modulation frequency, heat capacity, thermal conductivity, and coefficient of thermal expansion affect the signal. These equations, and generalizations of these equations, have been applied successfully to predict signal levels in a variety of experimental situations, as mentioned in the first paragraph of this section.

III CONCLUSIONS

The photothermal deflection techniques are highly sensitive techniques of 10% accuracy which find their greatest applicability in characterizing the effects on materials of production processes and handling. These non-contact, *in-situ* inspection techniques are in demand in both research and industrial applications in semiconductors and optics [17, 18], and photothermal techniques have been applied to a broad range of sample geometries and materials [7]. The localized nature of these techniques has revealed the fact that impurities, defects, and surface conditions alter dramatically the local absorption level of a material [61]. This has shown us that we must think of a material as having a distribution of absorption levels in order to anticipate the behavior of the material in modern research and technology. The extended techniques we mentioned in the introduction are used more commonly than the deflection techniques for measuring "the" optical constants of materials, because they average over the local variations. However, if one wishes to separate bulk from surface absorption in a transparent material, the ability to choose the measurement location with the beam crossing in the collinear-deflection technique is very useful. One must also realize that the local variations are hidden by the extended techniques—and turn to a local technique to get a complete picture of k in demanding applications.

q	acoustic phonon wavevector
ω	angular frequency in rad/s
ν	frequency in Hertz
n	complex index of refraction
η	index of refraction
κ	extinction coefficient
α_0	absorption coefficient
β_0	phase coefficient
λ_0	wavelength in vacuum
$\lambda_i = \lambda_0/\eta$	wavelength in sample
θ	scattering angle
Ω	Brillouin line frequency
v_s	velocity of sound
F_R	reflective finesse
Δ	free spectral range
t	spacing between Fabry-Perot plates
R	reflectivity of Fabry-Perot plates
c	speed of light in vacuum
Γ_q	damping constant of acoustic phonon
γ_q	sound attenuation constant
η_f	index of refraction of medium between the Fabry-Perot plates
δ	optical skin depth
α, β, γ	angles describing side and edge illumination for thin films
d	film thickness
Y	Young's modulus
σ	Poisson's ratio
ρ	density
P	Pockels coefficient

II INTRODUCTION

Brillouin scattering is known to be a very valuable tool to investigate the elastic properties of various materials. Typically, one can derive considerable information about the acoustic phonons from the measured Brillouin peaks. The shift and the width of the peaks can be directly related to the phonon velocity and the phonon attenuation constant, respectively.

In a pioneering work, Sandercock [1] showed, however, that the Brillouin-scattering technique can be applied also to measure the optical constants of absorbing materials and determined accurately the refractive index and the absorption coefficient of germanium and silicon. For this purpose he used a high-resolution, multipass Fabry-Perot interferometer to examine the broadening effect due to absorption on the Brillouin peaks of these materials. In this chapter we describe this broadening effect and its usefulness in measuring the optical constants of absorbing materials.

BACKGROUND ON BRILLOUIN SCATTERING TECHNIQUE

In a typical Brillouin-scattering experiment, a laser beam is directed onto a scattering medium. The scattered light passes through a Fabry-Perot interferometer and is then collected by a detector positioned at a scattering angle, θ, with respect to the incident beam. One obtains, in principle, the spectrum of scattered light (see Fig. 1) from the scattering sample—a plot of the distribution of scattered intensities as a function of frequency. The shape of the measured spectrum depends on the underlying physical processes responsible for the scattering phenomenon. The theoretical task is to identify these processes and calculate the corresponding spectral lineshape.

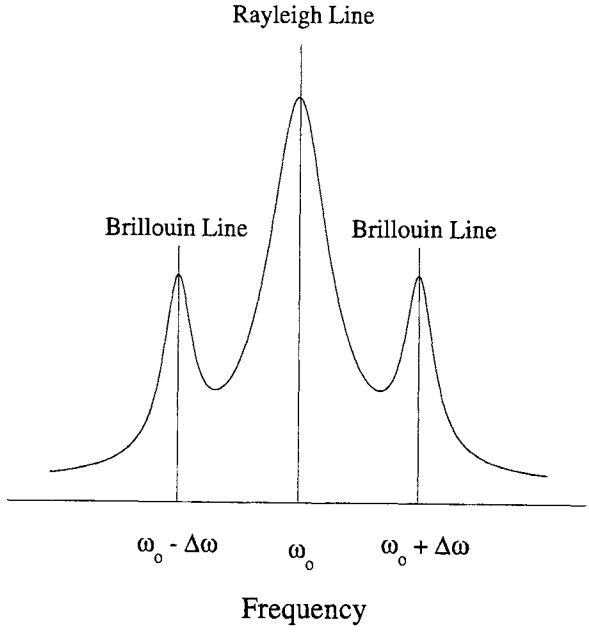

Fig. 1. Typical Brillouin spectrum of a fluid.

As an example, if we consider scattering from a single-component fluid sample, the spectrum of light scattered in a given direction contains three components for a fixed scattering geometry [2, 3]. First, a central Rayleigh line at a non-shifted frequency of the source. This elastic component is caused by density fluctuations in the fluid in thermodynamic equilibrium. These fluctuations cause, in turn, fluctuations in the dielectric constant responsible for the scattering of light. Second, two symmetric, shifted lines. These lines, commonly named Brillouin lines, are caused by inelastic scattering from longitudinal acoustic waves (phonons) propagating in the fluid at a frequency determined by the speed of sound.

In the case of crystals, the spectrum of most light-scattering experiments is composed of a central, non-shifted component and up to three pairs of the phonon components (Brillouin lines): one pair corresponds to longitudinal phonons, and two other pairs correspond to transverse phonons [4–6]. In contrast to the central component in fluids, the non-shifted line is caused by elastic scattering from imperfections either from the surface or bulk of the sample. The Brillouin lines are caused by a collective mode of vibrations of the molecules or atoms forming the sample crystal. We should mention that in crystals, additional components caused by other acoustic quasiparticles such as acoustic magnons, can appear in the spectrum [7].

In the following we will focus only on the Brillouin line as it pertains closely to the application of the Brillouin-scattering technique on the measurement of optical constants. First, there has been extensive progress in understanding and describing the details of the interaction of the incident beam with the scattering system, allowing the calculation of the complete spectral lineshape [4–6, 8]. Second, development of high-contrast, multipass Fabry-Perot interferometers has motivated several experimentalists into applying the Brillouin-scattering technique as a valuable tool in their investigation of elementary excitations in various materials. By increasing the contrast of the instrument, it is possible to detect the weak Brillouin lines and suppress the dominant Rayleigh line [1, 9–13].

The scattering processes can be examined within either a wave (classical) or a quasi-particle (quantum) picture. In the first picture the incident electromagnetic wave, $E \sim e^{i(\omega_i t - \mathbf{k}_i \mathbf{r})}$, is scattered, for example, by the sound waves acting as diffraction gratings. Here we define ω_i and $\mathbf{k}_i$ as the angular frequency and wavevector of the electric field. If the grating were fixed in space, the scattered light would have the frequency of the incident field, ω_i. However, since sound waves propagate with phase velocity, v_s, the gratings move with the same velocity as well. As a result, the back-reflected beam is reduced by a Doppler shift of $2v_s\omega_i/c_m$, c_m being the speed of light in the scattering medium [2]. One can further this analysis and apply the general Maxwell's equations coupled with the elastic properties of the materials to derive the scattering spectrum representing this Doppler-shift line, a challenging theoretical work for complicated structures of the system.

In the quasi-particle picture one can regard the same scattering process as inelastic collisions between photons and phonons [11]. The incident photon has an energy $\hbar\omega_i$ and momentum $\hbar\mathbf{k_i}$, whereas the scattered photon has an energy $\hbar\omega_s$ and momentum $\hbar\mathbf{k_s}$. Conservation of energy and momentum is then applied to extract the form of the normal-mode dispersion relations by requiring that

$$\hbar\mathbf{q} = \hbar\mathbf{k_i} \pm \hbar\mathbf{k_s} \quad (\textit{momentum conservation}), \tag{1}$$

$$\hbar\omega = \hbar\omega_i \pm \hbar\omega_s \quad (\textit{energy conservation}). \tag{2}$$

Two solutions are derived from the above relations: 1) $\mathbf{k_s} = \mathbf{q} - \mathbf{k_i}$ with $\omega_s = \omega - \omega_i$, and 2) $\mathbf{k_s} = \mathbf{k_i} - \mathbf{q}$ with $\omega_s = \omega_i - \omega$. The solutions $\mathbf{q}$ and ω correspond to the annihilation ("anti-Stokes") and creation ("Stokes") of a phonon, respectively. Note that in phonon creation, the scattered photon has a lower frequency than the incident photon, a consistent picture with red-shift tendency.

IV EQUATIONS FOR MEASUREMENT OF THE INDEX OF REFRACTION

We define the complex index of refraction as $n = \eta + i\kappa$, with κ as the extinction coefficient and η as the real-part of the index of refraction of the system (for simplicity we call η the index of refraction). Since our interest is in the measurement of η and κ of a material, our use of a measured Brillouin spectrum is directed to this purpose. So, unlike the common application of the Brillouin-scattering technique as a tool to investigate acoustic phonons in crystals or hydrodynamic modes in fluids, we intend to use the scattering property of the acoustic phonons to determine these optical constants. On the theoretical side, we need to determine the relation between η and κ of the scattering medium and the quantities that can be derived from the measured Brillouin spectrum. On the practical side, we need to design the appropriate spectrometer to measure accurately the Brillouin spectrum. More importantly, we need to discuss the limitations of the Brillouin-scattering technique.

We first note that the energy of acoustic phonons is, at most, of order $E = 10^{-2}$ eV, whereas energy of a visible photon is typically a few eV [11]. Second, for crystals the photon wavevectors are small (of order 10^5 cm^{-1}) compared with typical Brillouin-zone dimensions (of order 10^8 cm^{-1}) [11]. The length scale probed by visible light is long compared with distances between the atoms or molecules constituting the crystal, justifying the application of a continuum picture in the calculations. By applying the above observations, one can find that the magnitude of the wavevector of the incident photon in the medium is conserved in the scattering process. As a re-

sult the momentum-transfer vector q of the phonon probed by the experiment is given by:

$$q = |\mathbf{k_i} - \mathbf{k_s}| = 2k_i \sin(\theta/2), \tag{3}$$

with $|\mathbf{k_i}| = |\mathbf{k_s}|$ being the magnitude of the incident and scattering wavevectors inside the scattering medium. For a laser beam of wavelength λ_0 in vacuum, k_i is given by

$$k_i = \frac{2\pi\eta}{\lambda_0}, \tag{4}$$

where η is the index of refraction of the scattering medium.

The expression in Eq. (3) is commonly known as Bragg's condition. It is an exact relation for elastic scattering and an excellent approximation for most light-scattering situations. The q-value in Eq. (3) can be varied over a wide range by either varying θ or λ (see Eq. (4)) or both. For practical reasons, it is much easier to vary θ. In most experiments, however, θ is fixed and usually set at 90°, although backscattering configuration with $\theta = 180°$ has become a familiar configuration, especially for scattering from opaque materials and thin films.

A Scattering in Transparent Materials

In transparent materials ($\kappa = 0$) the wavevector of the probed phonon is determined uniquely by the wavelength of the incident laser beam and the scattering geometry, specifically the angle θ. The q-wavevector represents one specific Fourier-component of the phonon spectrum. For the observed Brillouin lines, the line shift, Ω, is directly related to the velocity of sound, v_s. This shift is

$$\Omega = v_s q = \frac{4\pi v_s \eta \sin(\theta/2)}{\lambda_0}, \tag{5}$$

where we use the expressions of Eqs. (3) and (4).

Immediately, one can see from Eq. (5) that the shift of the Brillouin line is directly proportional to the index of refraction. If v_s is known, η can be determined, since λ_0 and θ are known. If we neglect the width due to the inherent and natural lifetime of the scattering phonons as well as the width from the instrument (see Section B below), the lineshape of the Brillouin line is very sharp without a width, a theoretical $\delta(q)$-function centered at wavevector q, whose frequency is $\Omega = v_s q$. This can be explained by the uniqueness of the q-vector. The measured intensity is constructed from the

scattered electric fields that add up to form one single peak at the frequency, $\omega_i + \Omega$. Determination of η of transparent materials with such an approach is not commonly pursued, as η can be determined with higher precision using other optical techniques such as prism-minimum deviation and transmission-reflection techniques. The measured Brillouin spectrum is more appropriately used to determine v_s.

Scattering from Absorbing Materials B

Unlike transparent materials, absorbing materials are characterized by a complex refractive index, $n = \eta + i\kappa$, inducing a scale length over which the intensity of the optical field falls off exponentially in the medium. As the varying optical field traverses the material, a range of phonon wavevectors q is covered, adding up to the formed spectrum of the scattered beam [1, 12, 13]. This effect can be readily observed as a broadening of the Brillouin peaks. Here we note that this broadening is an additional effect to that due to the lifetime of the phonon.

For the backscattering configuration, two expressions have been applied to fit the observed Brillouin line, i.e., is, the distribution of the scattered intensity as a function of q wavevector. Initially, Sandercock [1] derived a Lorentzian distribution,

$$L(q) = \frac{1}{\pi} \frac{\alpha_0}{(\beta_0 - q)^2 + {\alpha_0}^2}, \tag{6}$$

where $\beta_0 = 2\omega_i\eta/c$ and $\alpha_0 = 2\omega_i\kappa/c$, ω_i being the angular frequency of the incident beam and c being the speed of light.

However, Dresselhaus and Pine [13] noted later that in the derivation of Eq. (6) the contribution from the reflected optical fields to the total spectrum was neglected. The lineshape of the Brillouin spectrum is not actually symmetric as the Lorentzian function of Eq. (6) suggests. For the same backscattering configuration, the lineshape is rather asymmetric around its maximum and is more accurately described by the following expression:

$$G(q) = \frac{Bq}{({\beta_0}^2 + {\alpha_0}^2 - q^2)^2 + (2q\alpha_0)^2}. \tag{7}$$

In contrast to Eq. (6), the expression in Eq. (7) vanishes at $q = 0$ and falls off as q^{-3} for large q. We further note that $G(q)$ in Eq. (7) and the Lorentzian in Eq. (6) are nearly identical in the limit of a weak absorbent ($\alpha_0 \ll \beta_0$). For a strong absorbent we have ($\alpha_0 \sim \beta_0$), and Eq. (7) appears to be appropriate to the real case.

The calculation for backscattering has been extended to an arbitrary direction of the incident beam [8, 12]. The situation becomes more complicated by the contribution of surface waves of the Rayleigh type to the scattered intensity. Further, the acoustic phonons (bulk) in solids are modified because longitudinal and transverse polarizations are coupled near the surface and cannot be considered independent.

V FABRY-PEROT INTERFEROMETERS

The frequency range of acoustic phonons falls in the Gigahertz, a range suitable to Fabry-Perot interferometers. Nowadays, high-resolution Fabry-Perot interferometers are commercially available and operated routinely to measure Brillouin spectra of various systems. A simple description of the interferometer and its principle of operation can be found in several textbooks [9, 10, 14]. In a simple design, a Fabry-Perot interferometer consists of two plane mirrors held parallel to each other. The inner surfaces are highly reflecting with a reflectivity exceeding 90%. If we examine the case of an ideal Fabry-Perot interferometer, where the plates are considered parallel and free of surface-defects, the instrumental function describing the interferometer is described by an Airy function:

$$I(\omega) = \frac{I_0}{[1 + F \sin^2(\pi\omega/\Delta)]}. \tag{8}$$

Equation (8) represents the lineshape that is obtained if an extremely narrow beam (described by a δ-like function) traverses the interferometer. In Eq. (8) we have $F = 4R/(1 - R)^2$ and $\Delta = c/2\eta_f t$ is the free spectral range, η_f being the index of the medium (usually air) between the mirror plates of reflectivity R, t the spacing between the plates, and c the speed of light in vacuum.

If one varies the spacing, t, or the index of refraction, η_f, one can change the condition of the transmission of light of a given frequency through the interferometer. If a scattered light contains two frequencies set at ω_0 and $\omega_0 + \delta\omega_0$ with ω_0 being at resonance frequency, the peak of the shifted line can be detected by varying t to cover at least one order of interference. Here the conditions for the observation of the shifted peak are determined by two important characteristics of the interferometer: finesse and contrast. First, the finesse, F_R, is the ratio of the free spectral range over the full width at half maximum of the Airy line and describes the capability of the instrument in separating various peaks. For an ideal interferometer it is defined as

$$F_R = \pi\sqrt{R}/(1 - R), \tag{9}$$

and depends only on the reflectivity.

Second, the contrast, C, is the ratio of the maximum over the minimum of the instrumental line, providing an idea on the power of the instrument to detect weak signals. For an ideal interferometer, it is given by

$$C = 1 + (4/\pi^2)F_R^2. \tag{10}$$

Both expressions of Eqs. (9) and (10) show that as R is increased, both finesse and contrast increase. In principle, one can then improve the performance of the interferometer by just changing R. However, imperfections such as surface defects and misalignment introduce a limit to the finesse and contrast [9, 10]. In the interferometers now available, F_R does not usually exceed ~ 50 and $C < 10^3$. This contrast number is particularly too small if one intends to measure very weak peaks, such as those of phonons in highly absorbing materials. For this purpose, a multipassing technique has been devised to increase the contrast [9, 10]. Here, the beam of light passes through the interferometer several times. It can be shown that the resultant contrast, C_n, is

$$C_n = C^n, \tag{11}$$

where n is the number of passes of the beam through the interferometer, and C is the contrast for one pass. In practice, two corner cubes are usually used to achieve multipassing by reflecting and appropriately directing the beam from the various facets of the two cubes. It is now possible to achieve a contrast as high as 10^{12}.

The schematic diagram of a typical set-up for the measurements of acoustic phonons by a multi-pass Fabry-Perot interferometer is shown in Fig. 2. The setup may operate either on 90°-geometry or in backscattering. The light of a laser beam (~200 mW) is focused and directed to a sample by the lens L_1 (90°) or L_2 (backscattering). The scattered light is collected by the lens L_2 and directed onto the input aperture of the Fabry-Perot interferometer. Here, the spacing between the plates t is scanned by piezoelectric rods to cover a number of orders of interference. The output beam passes through the collimator formed by the lenses L_2 and L_3, and is directed to a sensitive photomultiplier (PMT-1) usually with a low dark count (~1 ct/s). The output signal from the photomultiplier is amplified and further processed by a photon-counting circuit. The processed signal is fed to a multichannel analyzer. A second photomultiplier (PMT-2) in combination with a stabilization system is used in a feedback mode to control the plate separation by adjusting the piezoelectric spacers.

VI DISCUSSION

The main information obtained from a measured Brillouin spectrum are the line shift, the linewidth, and the distribution of intensity as a function of frequency, including the maximum peak.

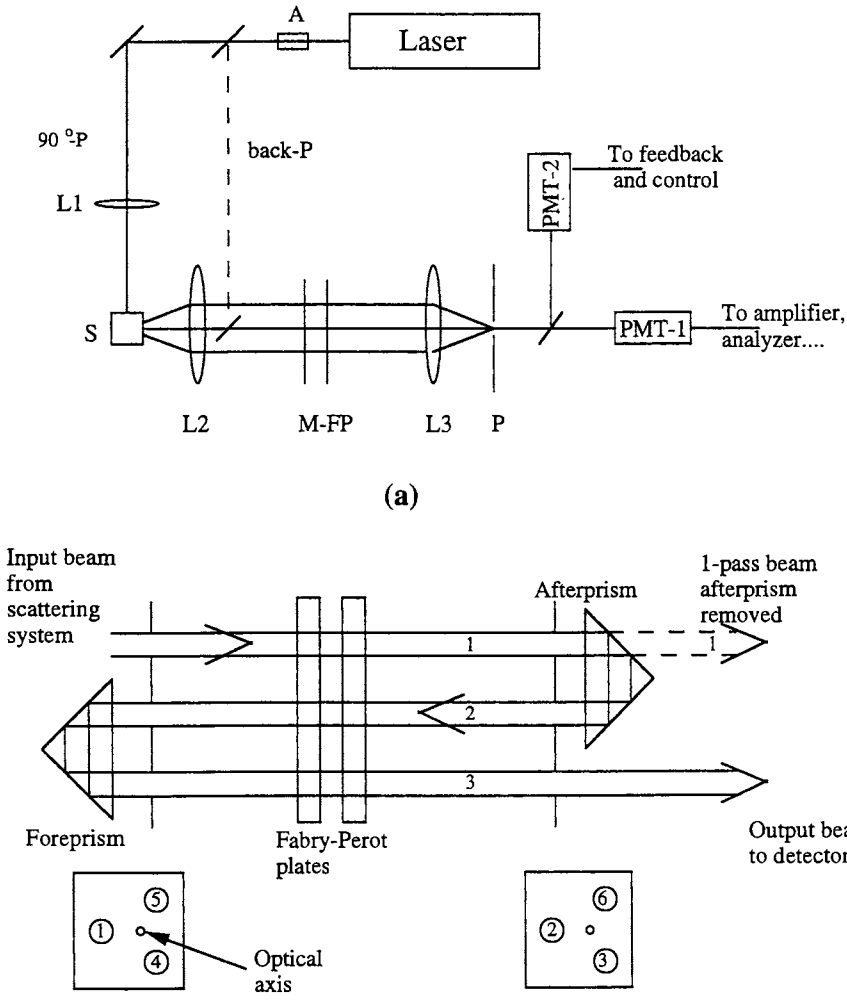

Fig. 2(a). Schematic diagram of an experimental setup to measure the Brillouin spectrum of a sample *S*. Two configurations are shown 90° (90°-*P*) and backscattering (back-*P*). L1, L2, and L3 are optical lenses, *M-FP* the Fabry-Perot interferometer, *P* the collecting pinhole, *PMT*-1 and *PMT*-2 the photomultiplier tubes. **(b)** Details of the 3-pass aperture and retroreflection prism of a 3-pass Fabry-Perot interferometer.

The line shift is directly related to the phonon velocity and is given by Eq. (5). Equation (5) shows that the shift depends on the velocity as well as the index of refraction. As discussed earlier for transparent materials, it is much more appropriate to use the Brillouin spectrum to determine the phonon velocity instead of η, since other optical techniques such as transmission-

reflection and prism-minimum deviation techniques are much more precise in measuring η. However, for practical reasons and experimental difficulties, the Brillouin-scattering technique is sometimes used to determine η. For example Zha *et al.* [15] applied the technique to investigate the effect of high pressure on transparent SiO_2 glass. For this purpose, they measured the Brillouin line shift at two different angles, 90° and 135°, (two q-vectors) and determined simultaneously both η and v_s from the ratio of the shifts. As the pressure was varied, they observed changes in η and v_s indicating changes in the structural properties of the glass. We should note, however, that this two-angle method is appropriate when the material is isotropic with one phonon velocity, therefore simplifying the problem. For anisotropic crystals, complications arise as the phonon velocity changes as a function of optical axis or q-vector. It is not possible then to separate η and v_s, since both vary as a function θ (q-vector).

Information on linewidth is much more useful in the case of absorbing materials as κ is related to the width. The experiments are performed in a backscattering configuration with a high-resolution, multi-pass Fabry-Perot interferometer, allowing the detection of weak Brillouin peaks [1, 16]. To get an accurate value of the width due to just broadening from absorption, corrections are needed to remove contributions from the phonon lifetime and the instrumental function that may include effects due to the finite size of the collection pinhole (see Refs. 9, 10, and 17–19 for more discussion).

Several methods have been developed to correct for contributions from the instrumental linewidth. One can fit the instrumental function with some familiar functions such as a Gaussian or Voigt function and deconvolute numerically the observed spectrum from the fitted instrumental function (see Refs. 17 and 18 and references therein). A more elaborate deconvolution scheme can be performed by first deriving an analytical form of the instrumental function (see Refs. 17–19 for more discussion). Here, the Airy function of the ideal Fabry-Perot interferometer is modified to include various defects in the instrument. Then, this analytical function is convoluted with the predicted scattering function (expression of Eq. (6) or Eq. (7) in our case). The resulting function is fit with the observed spectrum to determine the appropriate parameters (optical constants).

It is sometimes important to correct also for the broadening effect due to the finite size of the collecting pinhole on the spectrum. Indeed, the pinhole introduces a finite solid angle, collecting a range of q-wavevectors instead of the unique q defined in the above theoretical treatment. Experimentally, one has to compromise between reducing the pinhole size to avoid significant broadening and opening it to collect more signal [18].

In Table I we list η and κ for numerous materials which have been studied by Brillouin-scattering technique [20–36]. We should point out that only a few of these materials could yield linewidth information (Si, Ge, CdS, GaAs). Of particular interest is the ratio of the width of the lineshape to the

† Values for electric field polarization perpendicular to c-axis.

frequency shift. Assuming the lineshape to be Lorentzian, one can derive from Eq. (6)

$$\frac{\Delta\omega}{\Omega} = \frac{2\kappa}{\eta}, \tag{12}$$

where $\Delta\omega$ is the full width at half maximum of the line. Equation (12) can be expressed in terms of the absorption coefficient $\alpha_0 = 4\pi\kappa/\lambda_0$ or the skin depth $\delta = 1/\alpha_0$, yielding the following practical relation:

$$\frac{\Delta\omega}{\Omega} = \frac{2\kappa}{\eta} = \frac{\lambda_0}{2\pi\eta\delta}. \tag{13}$$

First, we emphasize that the relation in Eq. (12) is exact only when the lineshape is Lorentzian, a case applicable for low-absorbing materials such as Si. For highly absorbing systems such as Ge, the expression in Eq. (7) describes more accurately the measured lineshape, and Eq. (12) is just an approximation. We show in Fig. 3 the lineshape of the Brillouin lines of Si and Ge as measured by Sandercock [1]. Here we contrast the symmetric line observed for Si with the asymmetric line of Ge, a point already made by Dresselhaus and Pine [13].

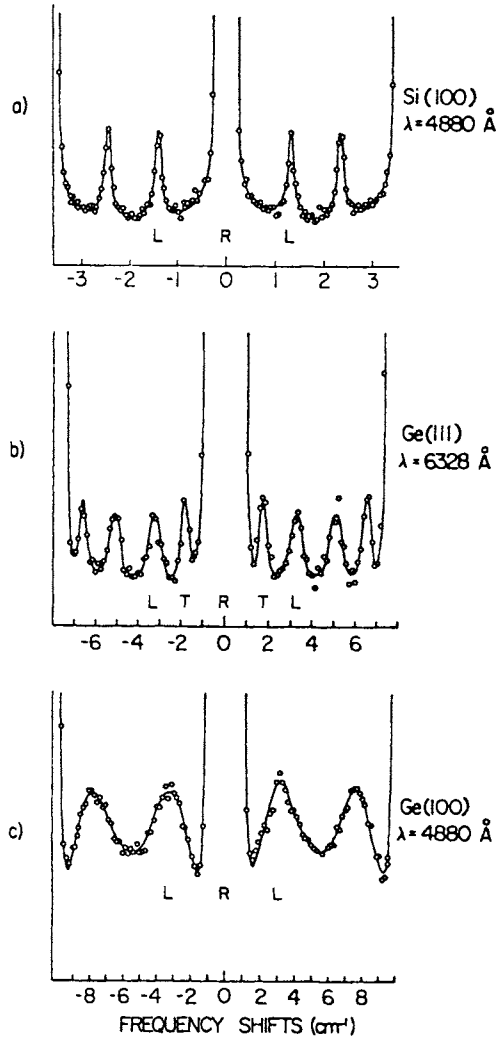

Fig. 3. Brillouin peaks of Si and Ge obtained by Sandercock [1].

Second, we note that the ratio, $\Delta\omega/\Omega$, can be obtained directly from the measured line. Sood and Cardona [16] measured the change in ratio $\Delta\omega/\Omega$ in Si as a function of concentration of a n-type dopant, which changes its absorption coefficient. We show in Fig. 4 their results. The determination of κ or η from the measured line requires previous knowledge of η or κ from another technique. If both η and κ are unknown, one needs the phonon velocity, v_s, which can be determined from ultrasonic measurements, for example. This approach was followed by Sandercock [1] in his analysis of his

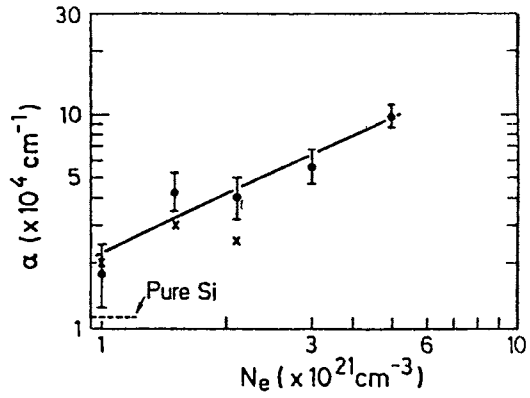

Fig. 4. Optical absorption coefficient of Si is shown as a function of concentration of dopant. The data were determined from the broadening of the measured Brillouin peaks. (From Sood and Cardona [16] with permission from the publisher.)

Si and Ge measurements. In this way, the Brillouin technique works as a complementary technique.

Third, Table I indicates further that the ratio in Eq. (12) becomes larger in highly absorbing materials such as metals. It may then be difficult to observe the peak, as its width can be larger than its frequency shift. Indeed, as κ is increased, the linewidth increases, extending the wings of the Brillouin peak to interfere with the next order of the Fabry-Perot lines. Another way, if the skin depth is of the order of the wavelength of the beam in the scattering medium ($\delta = \lambda_0/\eta$), Eq. 13 yields $\Delta\omega/\Omega \simeq 1/6$, showing a big broadening effect already. Since for metals, $\Delta\omega/\Omega \geq 2$, this is probably why bulk acoustic phonons have not been reported for metals. Practically speaking, materials with $0.01 < \Delta\omega/\Omega < 1$ show probably a measurable linewidth dependence on absorption.

VII BRILLOUIN SCATTERING IN THIN SLABS AND OPTICAL FIBERS

In the second part of this chapter, Brillouin scattering is considered in thin samples, such as thin slabs and single-mode optical fibers, where the dimension of the sample becomes of the same order as the light wavelength. Contrary to the bulk-sample case where both light and phonon energy and momentum are well defined, in thin samples, the light scattered over the thickness of the film develops an envelope of frequencies (and wavevectors), which, therefore, encompass more phonon energies and wavevectors. First, the formulas for calculating the refractive index in slabs are given for several convenient scattering geometries. Then, some examples of Brillouin spectra from the literature are considered, and the refractive index of the

samples is calculated using the given formulas. Finally, phonon propagation in thin slabs and single-mode fibers is discussed.

SPECIAL CASE OF TRANSPARENT THIN SLABS VIII

The refractive index η of a sample can be determined from the Brillouin shift Ω of an acoustic excitation or phonon from one of the two following relationships:

$$\Omega = \frac{4\pi v_s \eta}{\lambda_0} \sin\frac{\theta_s}{2}, \quad q = \frac{4\pi\eta}{\lambda_0} \sin\frac{\theta_s}{2}, \tag{14}$$

where v_s is the velocity of sound of the phonon generated by the light scattering, λ_0 is the wavelength of the incident light in vacuum, and θ_s is the scattering angle in the sample. The dispersion curve for acoustic phonons is given by $\Omega = \omega = qv_s$, where ω is often used, and q is the phonon wavevector. The Brillouin scattering in thin samples can be done by using side illumination [37–40] or edge illumination [40].

Side Illumination (90° External Scattering) A

Most Brillouin spectra in thin samples have been measured by using the side illumination, which is shown schematically in Fig. 5. In this figure, light is incident from the side of the sample (which has 1.458 refractive index, as that of silica), and the scattered light is observed at 90°. The internal scattered angle is not 90°. As can be seen from Fig. 5 (where the notation of Wang *et al.* [37] has been used), two different phonons are generated (created or destroyed depending on whether it is Stokes or anti-Stokes) with the refracted and reflected beams to produce the scattered light inside the sample. Note that for a typical material with $\eta = 1.5$, at a reflection most of the light is refracted out of the slab; only ~4% is reflected for modest angles of incidence. As shown in Fig. 5, in the first case, the phonon has q_1 wavevector, and the scattering angle is θ_1; while in the second case, the phonon has q_2 wavevector, and the scattering angle is θ_2. The two scattering angles can be determined from the following equations:

$$\theta_1 = \beta + \gamma, \quad \theta_2 = \pi - \beta + \gamma, \tag{15}$$

where β and γ are related to the refractive index η:

$$\eta\sin\beta = \sin\alpha, \quad \eta\sin\gamma = \cos\alpha, \tag{16}$$

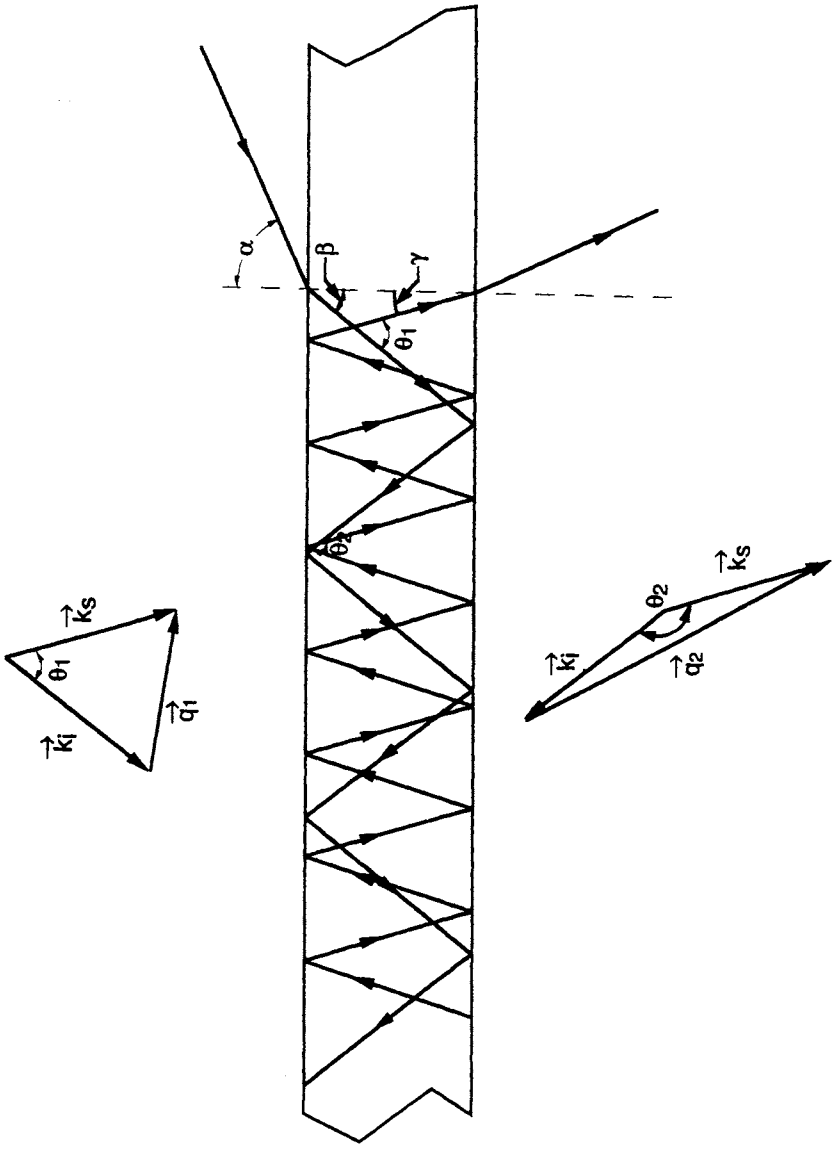

Fig. 5. Side illumination with 90° external scattering.

where α is the incident angle (not to be confused with the absorption coefficient, α_0) and β is the refraction angle (not to be confused with the phase coefficient, β_0). In the second Eq. (16), $\cos\alpha = \sin\alpha'$, since a 90° scattering is considered. Here, α' is the angle formed by the external scattered light and the normal to the sample surface. Note that in Fig. 5 the q_2 phonon is involved with near-backscattering internally.

Using the above equations, it can be shown that the phonon velocity v_s [Eq. (14)] can be expressed in terms of η and the incident angle α as follows [37]:

$$v_{s,1} = \frac{\Omega_1 \lambda_i}{[2\eta^2 + \sin 2\alpha - 2(\eta^4 - \eta^2 + \tfrac{1}{4}\sin^2 2\alpha)^{1/2}]^{1/2}}, \tag{17}$$

$$v_{s,2} = \frac{\Omega_2 \lambda_i}{[2\eta^2 + \sin 2\alpha + 2(\eta^4 - \eta^2 + \tfrac{1}{4}\sin^2 2\alpha)^{1/2}]^{1/2}}, \tag{18}$$

where Ω_1 and Ω_2 are the Brillouin shifts corresponding to the phonons with q_1 and q_2 wavevectors, respectively. For many transparent materials, one usually knows η in advance, so the phonon velocity is determined. For a cubic crystal oriented so that the principal axes are along the slab edges, these phonons will, in general, have different velocities. For an isotropic sample ($v_{s,1} = v_{s,2}$), from the above Eqs. (17) and (18), the following equation is obtained

$$\frac{{\Omega_1}^2}{{\Omega_2}^2} = \frac{2\eta^2 + \sin 2\alpha - 2(\eta^4 - \eta^2 + \tfrac{1}{4}\sin^2 2\alpha)^{1/2}}{2\eta^2 + \sin 2\alpha + 2(\eta^4 - \eta^2 + \tfrac{1}{4}\sin^2 2\alpha)^{1/2}}. \tag{19}$$

Fused silica can serve as an example of an isotropic sample. From this equation the refractive index η can be found from the Brillouin shifts Ω_1 and Ω_2 for any incident angle α.

45°–45° Scattering When the incident angle α is 45°, Eq. (19) has a very simple form. This geometry, in which the sample bisects the incident and the scattered light (45°–45°), has been used extensively in the literature to obtain the refractive index of thin samples and films [37–40]. In this case, $\beta = \gamma$ and $\alpha = 45°$ (see Fig. 5). The q_2 phonon is involved in internal backscattering. Then, from Eqs. (14), (15), and (16) one obtains:

$$v_{s,1} = \frac{\Omega_1 \lambda_i}{\sqrt{2}}, \tag{20}$$

$$v_{s,2} = \frac{\Omega_2 \lambda_i}{2\eta}. \tag{21}$$

Therefore, for an isotropic sample the refractive index η can be obtained from the following equation:

$$\eta = \frac{1}{\sqrt{2}} \frac{\Omega_2}{\Omega_1}. \tag{22}$$

B Edge Illumination (90° External Scattering)

This geometry, in which light is incident at the edge of the sample, has been discussed extensively by Takagi and Gammon [40], and it is shown schematically in Fig. 6. Our notation continues to be that found by Wang *et al.* [37]. One of the positive characteristics of this geometry is that the intensity of the phonon peaks is much stronger than that with the side illumination [40]. This is probably due to the larger volume per reflection implied by Fig. 6 compared to Fig. 5. Similarly to the side-illumination case, as can be seen from Fig. 6, two different phonons are involved in the scattering of the refracted and the reflected beams inside the sample. In the first case, the phonon has q_1 wavevector, and the scattering angle (inside the sample) is θ^*_1, while in the second case the phonon has q_2 wavevector, and the scattering angle is θ^*_2. The two scattering angles can be determined by the following equations:

$$\theta^*_1 = \pi - \beta - \gamma, \quad \theta^*_2 = \pi - \beta + \gamma, \tag{23}$$

where β and γ are related to the refractive index η through Eq. (16). Note that in Fig. 6, the q_2 phonon is involved with internal near-backscattering. Using Eqs. (14), (16), and (23) one obtains:

$$\nu^*_{s,1} = \frac{\Omega^*_1 \lambda_i}{[2\eta^2 - \sin 2\alpha + 2(\eta^4 - \eta^2 + \frac{1}{4}\sin^2 2\alpha)^{1/2}]^{1/2}}, \tag{24}$$

$$\nu^*_{s,2} = \frac{\Omega^*_2 \lambda_i}{[2\eta^2 + \sin 2\alpha + 2(\eta^4 - \eta^2 + \frac{1}{4}\sin^2 2\alpha)^{1/2}]^{1/2}}. \tag{25}$$

Note that Eqs. (18) and (25) are the same. From Eqs. (24) and (25) for an isotropic sample, we obtain the following equation:

$$\frac{\Omega^{*2}_1}{\Omega^{*2}_2} = \frac{2\eta^2 - \sin 2\alpha + 2(\eta^4 - \eta^2 + \frac{1}{4}\sin^2 2\alpha)^{1/2}}{2\eta^2 + \sin 2\alpha + 2(\eta^4 - \eta^2 + \frac{1}{4}\sin^2 2\alpha)^{1/2}}. \tag{26}$$

From this equation, the refractive index η can be found from the Brillouin shifts Ω^*_1 and Ω^*_2 for any incident angle α.

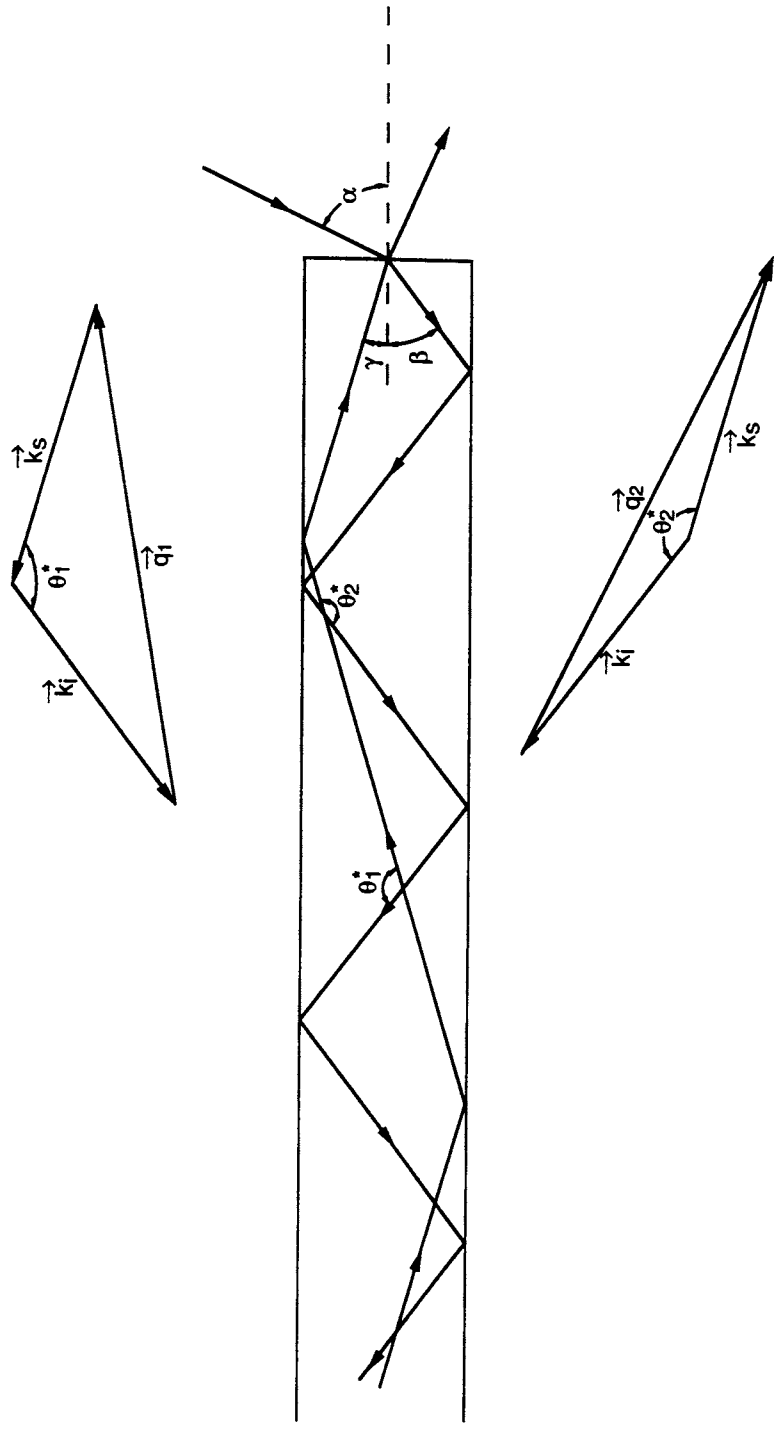

Fig. 6. Edge illumination with 90° external scattering.

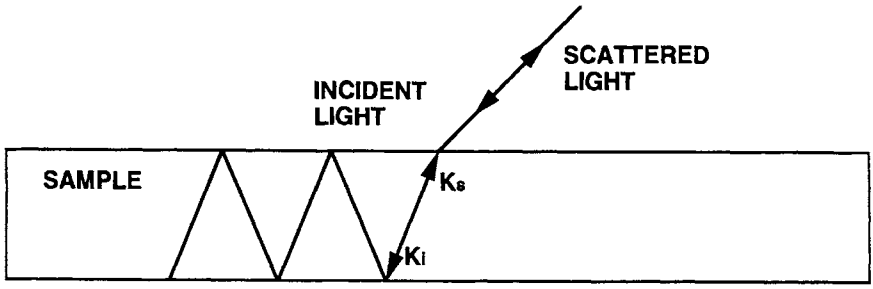

Fig. 7. Side illumination with 180° external backscattering.

45°–45° Scattering In this geometry we have $\beta = \gamma$ and $\alpha = 45°$. The q_2 phonon is involved exactly in backscattering internally. Then, from Eqs. (14), (16), and (23) one obtains:

$$v_{s,1} = \frac{\Omega^*{}_1 \lambda_i}{\sqrt{2}(2\eta^2 - 1)^{1/2}}, \tag{27}$$

$$v_{s,2} = \frac{\Omega^*{}_2 \lambda_i}{2\eta}. \tag{28}$$

Note that Eqs. (21) and (28) are the same. Therefore, the refractive index of an isotropic sample can be found from the following equation:

$$\eta = \frac{1}{\sqrt{2}[1 - \Omega^{*2}{}_1/\Omega^{*2}{}_2]^{1/2}}. \tag{29}$$

C Special Geometries

1 *External Backscattering*

Two examples of external backscattering (rather than 90° external scattering) are shown in Figs. 7 and 8, where backscattering is done from the side and the edge of the thin slab. For external backscattering for both side and edge illumination, the same phonon with wavevector q_2 is observed as described by Eqs. (18) and (25) or for the 45°–45° position, by Eqs. (21) and (28). Note that since only one q_2 phonon is observed (and q_2 is along k_s), Eqs. (17) and (24) are not pertinent. These results hold for an isotropic material or for a cubic material with the principal crystal axes along the edges of the thin slab. For an isotropic sample it can be shown from selection-rule analysis that for the backscattering geometry (180°), only the longitudinal phonon will be present, while no transverse phonon can be seen [41].

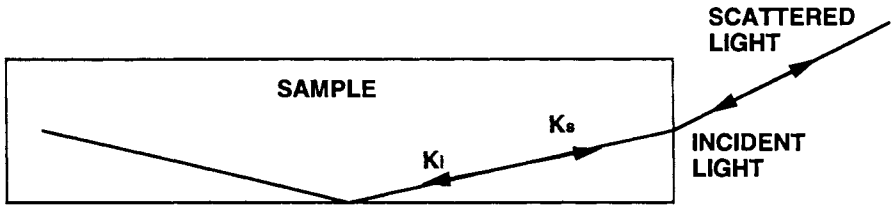

Fig. 8. Edge illumination with 180° external backscattering.

Classical 90° Scattering 2

For the traditional 90° scattering from a bulk sample shown in Fig. 9, $\theta_s = 90°$ in Eq. (14) and, thus:

$$v_s = \frac{\Omega\lambda_i}{\sqrt{2}\eta}. \tag{30}$$

Note that the phonon propagates at 45° to the plate edge. Contrary to the backscattering case, in the 90° scattering both the longitudinal phonon and the transverse phonons (only one transverse phonon for an isotropic sample) will be present.

Examples D

Here, some Brillouin spectra from thin plates and films are used from the literature to calculate their refractive index.

Isotropic Samples 1

Glass Plate The Brillouin spectra of a thin glass plate (150 μm thick) for the 45°–45° geometry for the side and edge illumination, is shown in

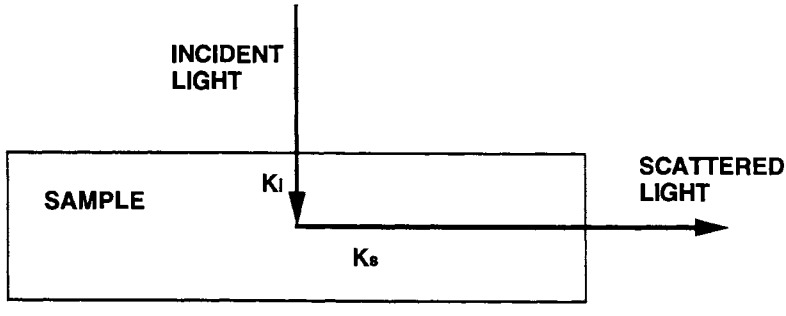

Fig. 9. Classical 90° scattering.

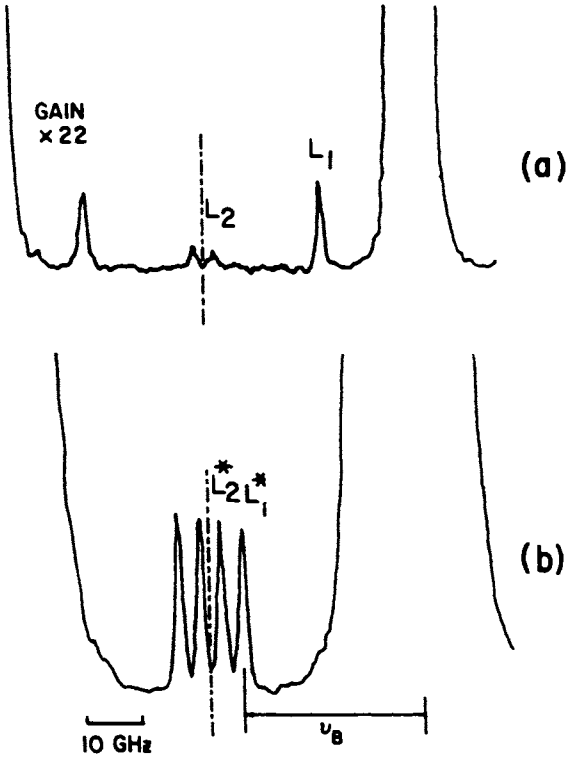

Fig. 10. Typical Brillouin spectra of thin glass plate (150 μm thick). $FSR = 77$; $\alpha = 45°$. (a) Side illumination; (b) Edge illumination. (After Takagi and Gammon [40].)

Fig. 10 [40]. The spectra were obtained using the VV scattering geometry, where only the longitudinal phonons can be seen for an isotropic sample.

In Fig. 10(a) the side illumination was used to obtain the ratio of the Brillouin shifts of the two longitudinal phonons L_1 and L_2 (with q_1 and q_2 wavevectors in Figs. 5 and 6). Then, using this ratio from Eq. (22), the refractive index of the isotropic thin glass plate is calculated to be 1.52.

In Fig. 10(b) the edge illumination was used to obtain the ratio of the Brillouin shifts of the two longitudinal phonons L^*_1 and L^*_2. Using this ratio, from Eq. (29) the refractive index of the thin glass plate is calculated to be 1.51, which is close to the 1.52 obtained from the side illumination. While this type of glass was not described, the fused-silica refractive index is 1.458, which is close to that obtained above.

Polymer Film: Mylar-PET The Brillouin spectra obtained from a polymer film, Mylar-PET, which is a commercial film used as a transparency sheet for overhead projectors can be seen elsewhere [40]. In this case, the side illumination and the 45°–45° scattering geometry were used to obtain

the Brillouin spectra shown in Fig. 11. From the ratio of the Brillouin shifts of the two longitudinal phonons L_1 and L_2, the refractive index of the isotropic Mylar-PET film is found from Eq. (22) to be 1.28. Most plastics have refractive indexes in the range 1.42–1.65, so this value appears too low [42, 43].

DNA Films The refractive index and the sound speed of DNA films has been studied using backscattering and 45°–45° geometry [39]. It was found that the refractive index decreases as the relative humidity of the DNA films increases (for dry DNA, $\eta = 1.50$).

Uniaxially Stretched Films 2

For nonisotropic films, the formulas given above for determining the refractive index are not expected to hold.

PET Film Brillouin scattering has been used in polyethylene terephalate (PET) films to study the sound velocity and the elastic constants as a function of the film stretching ratio [38]. The refractive index of the unoriented PET film is 1.588 at 4880 Å, which is within the range of plastics [42, 43]. It was found that, even though the refractive index of the film is not sensitive to stretching, the elastic constants strongly depend on the stretching ratio of the uniaxially stretched film [38]. The refractive index of the uniaxially stretched PET was found from the Brillouin spectra (side excitation; 45°–45° geometry) [38] using Eq. (22) to be 1.06, a value too low for plastics [42, 43]. This discrepancy is due probably to the fact that Eq. (22) holds only for isotropic samples.

Polyvinylidene Fluoride (PVF_2) Films Brillouin scattering was also used to study the sound velocity and the elastic constants of uniaxially stretched PVF_2 films [37]. Similar to the PET case, while the refractive index is not

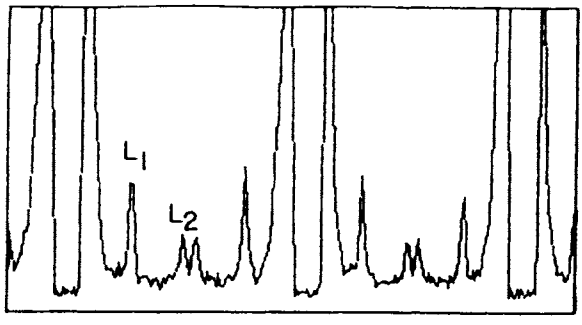

Fig. 11. Brillouin spectra of polymer film Mylar-PET with side illumination. *FSR* = 40 GHz. (After Takagi and Gammon [40].)

sensitive to stretching ($\eta = 1.43$), the sound velocity and the elastic constants are sensitive to the stretching ratio. From the Brillouin spectra (side illumination; 45°–45° geometry) seen elsewhere [37], it was found (using Eq. (22)) that the refractive index of the PVF_2 in the form I is 1.05, while in the form II it is 1.02, values too low for plastics. As in the previous case, this discrepancy is due probably to the fact that the film is not isotropic.

E Side Illumination at Normal Incidence

Brillouin scattering has been used to study phonon propagation in thin films. Following Sandercock [44], for the case of backscattering (180°) perpendicular to the film surface, we have the following distinct regimes.

a. With a real refractive index η, for a semi-infinite thick film, the Brillouin spectrum is typical with the normal Brillouin shift $\Omega = 2\eta k_0 v_s$, as illustrated in Fig. 12(a), where some instrumental and phonon-lifetime broadening of the peaks has been assumed.

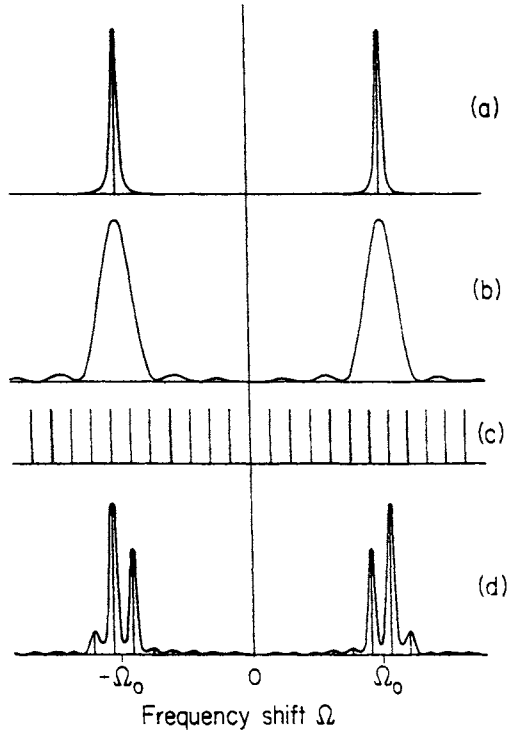

Fig. 12. (a) A normal Brillouin spectrum, (b) the expected spectrum from a thin supported film, (c) the possible frequency shifts in the spectrum from a thin unsupported film, and (d) the observable spectrum from a thin unsupported film. (After Sandercock [44].)

b. With a real η, there is a special case of a film supported on a substrate with the special properties that the substrate has the same acoustic impedance (so phonons can propagate across the boundary freely), but the substrate has very different elasto-optic properties, so that scattering occurring in the film is distinguishable from scattering in the substrate. Such a film/substrate sample probably does not exist, so the spectrum in Fig. 12(b) is not observable. Since film and substrate have the same acoustic properties, all values of q perpendicular to the surface are allowed. However, the Brillouin peaks are broadened due to the finite summation of the scattered electric fields as the incident beam traverses the film. The line shape is given by a $\sin^2 x/x^2$, as shown schematically in Fig. 12(b). Here, $x = (\Omega_0 - \Omega)d/2v_s$, where d is the film thickness, Ω_0 is the Brillouin shift corresponding to the phonon frequency, and Ω is the variable frequency.
c. If further, the film is unsupported, the boundary conditions require that the component of the phonon wavevector perpendicular to the surface be an integral multiple of π/d. In this case, the Brillouin spectrum would have peaks at the frequency shifts $\Omega = qv_s = p\pi v_s/d$ (p is an integer), as shown in Fig. 8(c).
d. Moreover, these phonon lines have a relative amplitude determined by the $\sin^2 x/x^2$ envelope (Fig. 8(b)). Thus, the resulting Brillouin spectrum will be similar to that shown in Fig. 12(d), where again, some instrumental and lifetime broadening has been assumed. The exact form of the peaks of Fig. 12(d) depends on the thickness d, but in general they show triplet or quadruplet structure within the main peak of the $\sin^2 x/x^2$ envelope. With reference to the dispersion curve shown schematically in Fig. 13, the quantized acoustic-phonon modes would be along the q-axis, while the measured phonon frequencies would occur along the ω-axis. Furthermore, the observed modes would be attenuated severely.
e. With a complex index of refraction n, a near-Lorentzian broadening of the Brillouin peaks occurs, as has been discussed in Section IVB. Therefore, the Brillouin components in Fig. 12(d) should be broadened.

From the above discussion the main conclusion is that while normal Brillouin scattering (from a large volume) determines precisely both the energy (from the spectrum) and the momentum (from the scattering geometry) of the phonon involved, the backscattering from a thin film normal to the surface measures phonons within a range of momenta and correspondingly, having a range of energies.

The predicted triplet in the Brillouin spectrum of a thin unsupported film (Fig. 12(d)) has been observed experimentally in Mn_2PS_4 films [44]. Figure 14 shows the observed Brillouin spectrum from two specimens of Mn_2PS_4 of thickness 1.1 and 2.0 μm. In both these spectra the triplets are clear; as the thickness of the film increases, however, the secondary peaks of the triplet get much weaker (Fig. 14(b)).

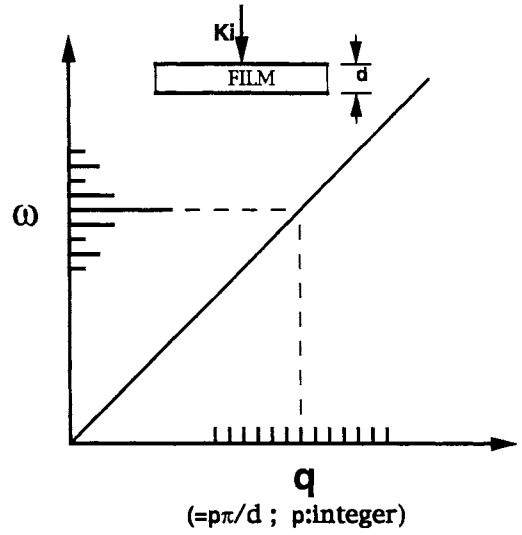

Fig. 13. Frequency vs. wavevector for acoustic phonons propagating perpendicular to the surface of a thin unsupported film. While the incident light energy and wavevector are well defined, the light backscattered over the thickness of the film contains an envelope of frequencies which contain several of the phonons, thus giving the multiple structure.

IX BRILLOUIN SCATTERING IN OPTICAL FIBERS

Brillouin scattering has also been used to study phonon propagation in optical fibers. Most of the work has been done with single-mode fibers in the core of which only one optical mode (photon) propagates. The core is surrounded by the cladding (clad) which has a slightly lower refractive index than that of the core, so that light can propagate in the core in a total-internal-reflection mode. In the simplest case of the backscattering geometry, which we consider here and in which only the longitudinal phonon is present, both the phonon and the photon are propagating almost along the fiber axis. Similar to the thin-film case, phonon propagation in single-mode fibers is expected to be strongly affected by the boundary conditions at the core-clad interface, since light is confined to propagate in the fiber core, which has a diameter (few microns) of the same order as the propagating light wavelength. Indeed, it has been found that [45]: the normal acoustic modes are linear combinations of transverse and longitudinal phonons in both the core and the clad, and the relative field amplitudes are dependent on the boundary conditions at both surfaces. Second, the density of phonon states is not uniform in q and ω space. Finally, the wavevector is not conserved in this acousto-optic interaction for a direction normal to the surface, i.e., the radial direction, and scattering is allowed over a continuum of phonons.

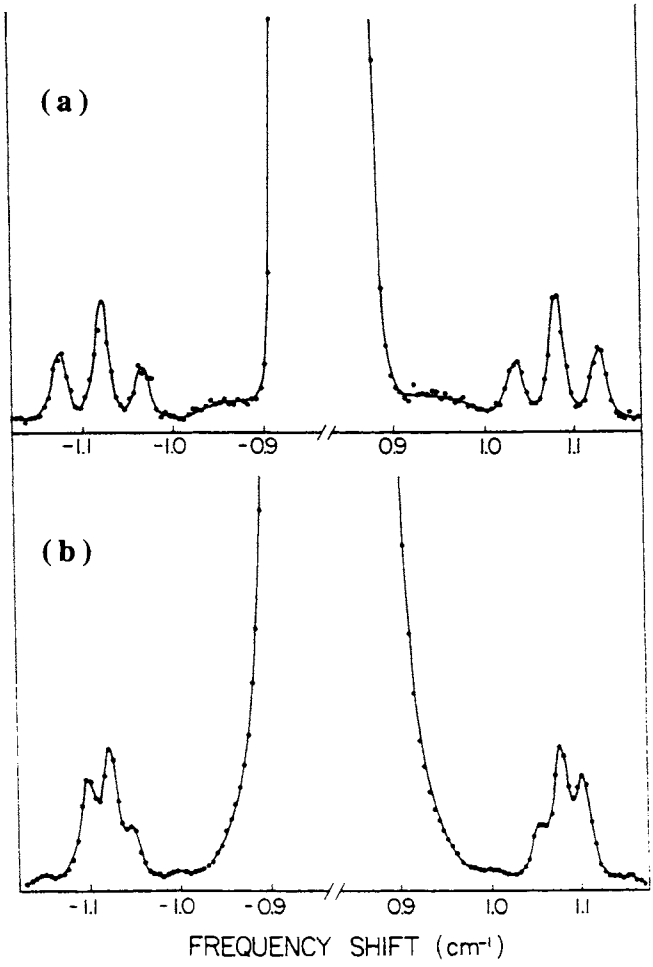

Fig. 14. Observed spectra from (a) and (b) two specimens of Mn_2PS_4 of thickness 1.1 and 2.0 μm, respectively. After Sandercock [44].

Even with the added complexities of a cylinder compared with a flat plate, some comparison can be made with the results for plates given in Eqs. (14–28).

Examples A

Brillouin scattering in optical fibers has been done using 180° and 90° geometry, which are shown schematically in Fig. 15.

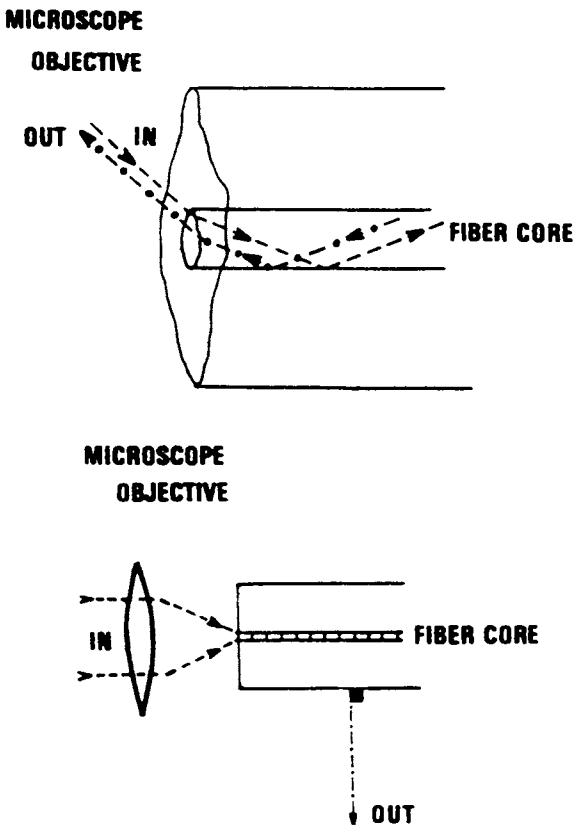

Fig. 15. Schematic of Brillouin scattering in an optical fiber (a) 180° scattering; (b) 90° scattering. After Thomas *et al.* [45].

1 *180° Scattering*

Using the Brillouin backscattering shown in Fig. 15, in which only the longitudinal phonon can be seen, phonon propagation has been studied in single-mode fibers (3 μm core diameter), which is shown in Fig. 16 [45]. In this figure we can see the longitudinal phonons propagating in the core only and in the core-clad space. In Thomas *et al.* [45] the refractive indexes of the core and the clad are given to be 1.462 and 1.457, respectively. From the spectrum of Fig. 16 and the refractive indexes, the sound velocities were calculated using Eq. (28) (backscattering phonon):

$$v_c = 6.026 \times 10^5 \quad \text{cm/sec}, \quad v_{cl} = 5.160 \times 10^5 \quad \text{cm/sec}. \tag{31}$$

Using Eq. (28), which has been derived for thin slabs, is an approximation for the cylindrical fibers, and it probably holds only for the optical rays passing through the fiber axis. These rays propagate in planes containing the

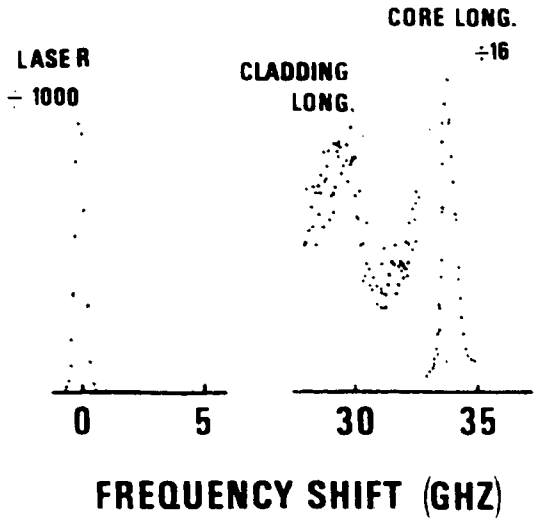

Fig. 16. Experimental Brillouin spectrum from a single optical fiber (180° scattering geometry). (After Thomas *et al.* [45].)

fiber axis. For the skew rays which do not pass through the fiber axis, the above equations would not hold; however, the skew modes attenuate fast in a fiber, and in the steady state of propagation only the rays passing through the center are present.

Even though the exact composition of the fiber was not given, as it can be seen below, the velocities listed in Eq. (31) correspond to standard fibers. In this example, the refractive indexes were given, and the sound velocities were found. However, the opposite is also true: Given the sound velocity, the refractive index can be found using the formula of Eq. (25) or (28).

90° Scattering 2

Single-Mode Fiber Using the 90° scattering shown in Fig. 15, the Brillouin spectrum was obtained in the fiber which was also used in Fig. 16, which is shown schematically in Fig. 17. This spectrum contains both the longitudinal phonons of the core and the clad and the transverse phonon of the core. For the Brillouin shift of the longitudinal core phonon (23.9 GHz), using Eq. (30), it is found that $\eta = 1.463$, a value very close to 1.462 found from the backscattering experiment of Fig. 16.

Single-Mode Fiber Preforms The elastic and elasto-optic (Pockels) coefficients of single-mode fibers have been studied doing Brillouin scattering

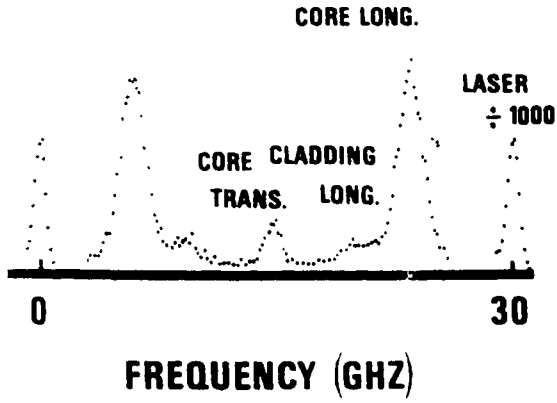

Fig. 17. Experimental Brillouin scattering from an optical fiber (classical 90° scattering geometry). (After Thomas *et al.* [45].)

(90°) on the glass preforms from which the fibers were drawn [46]. The preforms were cylinders 5 cm long and 7 mm in diameter with optically polished end faces. Two different fiber preforms were studied, one with numerical aperture $NA = 0.1$ composed of a fused-silica core with traces of GeO_2, and a clad of 5% B_2O_3 + 95% SiO_2 and another with $NA = 0.15$ composed of a 3% GeO_2 + 97% SiO_2 core, and a 15% B_2O_3 + 85% SiO_2 clad. The longitudinal (L) and the transverse (T) phonons were studied from the (V,V) and the (V,H) Brillouin spectra, respectively. The sound velocities of the phonons were calculated from Eq. (30), where the refractive index had been obtained using the prism method. From the two sound speeds, for an isotropic sample the elastic moduli, i.e., Young's modulus Y and Poisson's ratio σ, can be calculated using the following formulas:

$$Y = \rho v_T^2 \frac{(3v_L^2 - 4v_T^2)}{v_L^2 - v_T^2}, \quad \sigma = \frac{v_L^2 - 2v_T^2}{2(v_L^2 - v_T^2)}, \tag{32}$$

where ρ is the glass density.

The Pockels coefficients were also found by comparing the Brillouin spectra of the preforms to that of a fused-silica preform, whose Pockels coefficients are known, using the following formula for the L phonon [6]:

$$I = \frac{K\eta^8 P_{12}^2}{\rho v_s^2}, \tag{33}$$

where K is a geometrical and temperature factor, and P_{12} is the Pockels coefficient. Keeping the scattering geometry of the fused silica and the preforms identical, the K factor was eliminated by dividing the intensities of the spectra of the fused silica by those of the preforms [46]. This demonstrates the power of the Brillouin-scattering spectra from which, not only all the elastic moduli can be determined at once, but also the (very difficult to

measure) Pockels coefficients can by obtained. It should be also noticed from Eq. (33) that the intensity of the Brillouin spectra has the very strong dependence on the 8th power of the refractive index η.

The results of these experiments on the two fiber preforms for the coefficients of the longitudinal phonon for the core and the clad are listed below: Fiber $NA = 0.1$:

$$\eta_c = 1.4580, \quad \eta_{cl} = 1.4546, \quad v_{c,L} = 5.944 \times 10^5 \text{ cm/sec}, \quad v_{cl,L} = 5.605 \times 10^5 \text{ cm/sec}. \tag{34}$$

Fiber $NA = 0.15$:

$$\eta_c = 1.4624, \quad \eta_{cl} = 1.4547, \quad v_{c,L} = 5.806 \times 10^5 \text{ cm/sec}, \quad v_{cl,L} = 5.164 \times 10^5 \text{ cm/sec}. \tag{35}$$

A close comparison of the sound velocities in Eq. (31) to those in Eqs. (34) and (35) identifies the composition of the fiber used in the 180° scattering to be close to that of the 0.15 *NA*. Also the refractive indexes of these two glasses are very close ($\eta_c = 1.462$ vs. 1.4624, $\eta_{cl} = 1.457$ vs. 1.4547).

Edge Illumination (90° External Scattering) 3

Pyrex Glass The edge illumination (90° external scattering) has been used [40] to obtain the Brillouin spectrum of the longitudinal phonon of a 600 μm diameter glass rod (Pyrex), which is shown in Fig. 18(a). The incidence angle was ~45° for the 45°–45° geometry [47]. If the slab model holds for the cylinder, which seems to be the case in the examples above, two phonons should be observed in the cylinder. If $\Omega_1{}^{*2}/\Omega_2{}^{*2} = 0.844$ is obtained from Fig. 18(a), $\eta = 1.8$ is calculated from Eq. (29), while for Pyrex $\eta = 1.471$ [48]. The correct value for the refractive index of Pyrex can be found from Eq. (26) with $\alpha = 20°$ or 69° for the angle of incidence. Only with these incidence angles for a 90° external scattering, can the peaks shown in Fig. 18(a) correspond to $L_1{}^*$ and $L_2{}^*$ phonons discussed in Section VIII.B, as has been assumed by Takagi and Gammon [40].

Optical Fibers The Brillouin spectra of a multimode and a single-mode fiber are also given and are shown in Figs. 18(b) and 18(c), respectively [40]. For the multimode fiber, $\Omega_1{}^{*2}/\Omega_2{}^{*2} = 0.855$ (Fig. 18(b)), which gives $\eta = 1.8$ for the 45°–45° geometry; this is too large for an optical fiber, which is probably a high-silica glass. Conversely, Eq. (26) gives $\alpha = 17°$ or 72° (with $\eta = 1.458$ for silica), which is not in agreement with experiment.

For the single-mode fiber, $\Omega_1{}^{*2}/\Omega_2{}^{*2} = 0.849$ (Fig. 18(c)), which gives $\eta = 1.8$ for the 45°–45° geometry; again, this is too large for an optical fi-

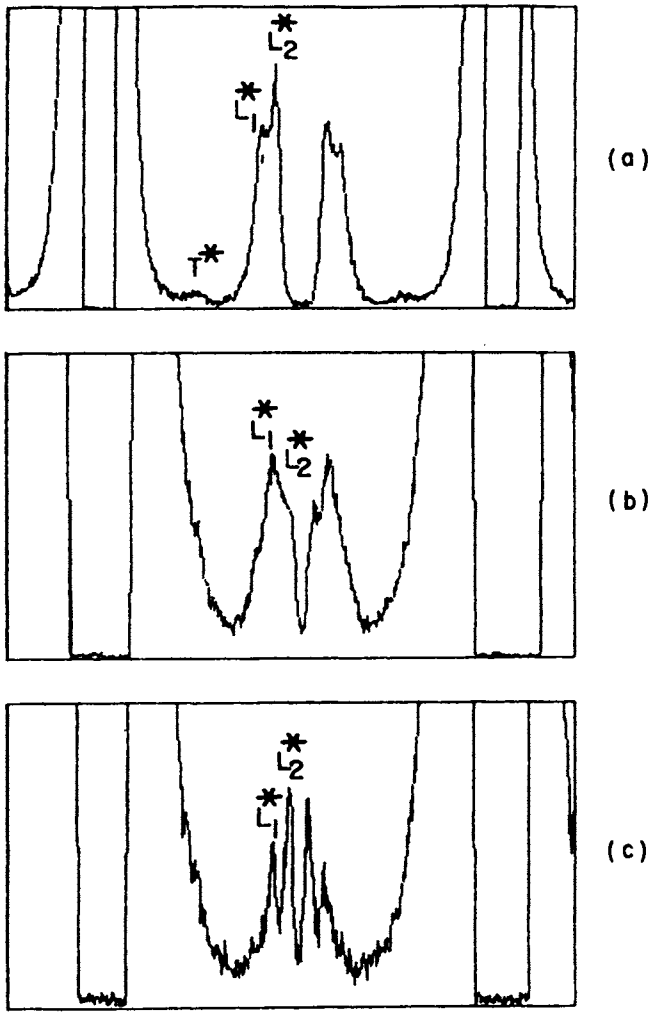

Fig. 18. Brillouin spectra with edge illumination at $FSR = 77$ GHz; (a) glass rod (600 μm), (b) multimode optical fiber, and (c) single-mode optical fiber. After Takagi and Gammon [40].

ber. Conversely, Eq. (26) gives $\alpha = 19°$ or $71°$, which is not in agreement with experiment.

However, for the case of the fibers another possibility is that the two longitudinal phonons correspond to the core and the clad phonons, similar to the ones observed in Figs. 16 and 17, and not to the L_1* and L_2* phonons, as were assigned by Tagaki and Gammon [40].

INTRODUCTION I

The importance of knowing optical constants was excellently outlined in the introduction to *HOC I* [1]. In the case of silicon, one can also point out technologically important applications of this knowledge. A partial list includes the determination of epilayer thickness [2] and the losses in all-silicon integrated optical devices [3], silicon-wafer thermometry [4], IR emissivity, and absorbance enhancement in silicon gratings [5, 6]

To be self-contained, this critique includes an overview of dielectric-function partition and the relation of optical constants to measured optical properties (Section II), semiclassical, and quantum absorption theory (Sections III and IV). In order to avoid multiple repetition when citing textbook materials, we refer in advance to well-known books on optics [7], semiconductor optics [8], and physics [9], and quantum mechanics [10]; in Section IV we also introduce the generalized Drude approximation. Section V is an

overview of experimental data and the Drude formula with empirically adjusted parameters. In Section VI we present a first-principle theory of free-carrier contribution to optical constants in doped n-Si based on the generalized Drude approximation. We outline the calculations and emphasize the difficulties that the theory is faced with when being used to describe available experimental data.

II CONTRIBUTIONS TO DIELECTRIC FUNCTION: OPTICAL PROPERTIES VERSUS OPTICAL CONSTANTS

Electromagnetics of homogeneous material is completely defined by the dielectric function (DF): $\epsilon = \epsilon_1 + i\epsilon_2$, a function of radiation frequency ω or vacuum wavelength $\lambda = 2\pi c/\omega$. The basic quantity of optics, however, is *complex refractive index* $\sqrt{\epsilon} = n + ik$, where the *refractive index, n,* and *extinction coefficient, k,* are related to ϵ_1 and ϵ_2 via equations

$$n^2 - k^2 = \epsilon_1, \tag{1}$$

$$2nk = \epsilon_2. \tag{2}$$

The lattice and free-carriers, which arise from doping, give additive contributions to the DF:

$$\epsilon = \epsilon_l + \epsilon_c. \tag{3}$$

Here, $\epsilon_l = (n_l + ik_l)^2$ is the lattice contribution, and ϵ_c is that due to the carriers

$$\epsilon_c = i\frac{4\pi\sigma(\omega)}{\omega}, \tag{4}$$

where $\sigma(\omega)$ is conductivity at optical frequencies. Though doping also affects $\epsilon_l$via band-gap reduction [11], in the IR this effect is negligible as compared to ϵ_c. The tables of n_l and k_l for intrinsic silicon were presented by Edwards [12]; such tables for Si: O_2 were also reported [13]. In the near and mid IR, n_l decreases from 3.4490 at 5000 cm^{-1} to 3.4201 at 400 cm^{-1}, the largest values of $k_l \sim 10^{-3}$ are achieved in a narrow band near 606 cm^{-1}. It seems that this variation is negligible on the scale of ϵ_c for doping in excess of 10^{16} cm^{-3}; in most papers, n_l is taken to be constant, and k_l is neglected.

Experimentally, n and k are determined using measurements of various optical properties of quality samples with simple geometry. For smooth

opaque samples, the only quantity of interest is the complex amplitude reflectance

$$r = -\frac{\sqrt{\epsilon} - 1}{\sqrt{\epsilon} + 1} = \sqrt{R}\exp(i\Phi), \tag{5}$$

where R is the Fresnel reflectance of the sample's surface

$$R = |r|^2 = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2}, \tag{6}$$

and Φ is the argument of the complex reflectance

$$\tan(\Phi) = \frac{2k}{n^2 + k^2 - 1}. \tag{7}$$

The spectrum of R is measured using reflectometry techniques; with R measured, Φ is determined using Kramers-Kronig analysis (KKA) [14]. With both spectra available, Eqs. (6, 7) are solved simultaneously to yield n and k. For a transparent slab, the apparent reflectance R_a and transmittance T_a are measured. In many practical cases, interference oscillations (fringes) in the spectra of R_a and T_a are averaged out. This leads to simple equations:

$$R_a = R\left[1 + \left|1 - r^2\right|^2 \frac{\exp(-2\alpha d)}{1 - R^2\exp(-2\alpha d)}\right], \tag{8}$$

$$T_a = \left|1 - r^2\right|^2 \frac{\exp(-\alpha d)}{1 - R^2\exp(-2\alpha d)}, \tag{9}$$

in which d is the thickness of the slab, and

$$\alpha = \frac{4\pi k}{\lambda} \tag{10}$$

is the EM *power attenuation coefficient.* It is referred to as the *absorption coefficient* in the case $n > k$ ($\epsilon_1 > \epsilon_2$). At $n \gg k$, $r^2 = R$ in Eqs. (8, 9), and *spectral absorbance* $A = 1 - R_a - T_a$ takes the following form when used in silicon-wafer thermometry [4]:

$$A = \frac{(1-R)[1 - \exp(-\alpha d)]}{1 - R\exp(-\alpha d)}. \tag{11}$$

III SEMICLASSICAL THEORY OF FREE-CARRIER CONTRIBUTION TO THE DIELECTRIC FUNCTION: THE DRUDE APPROXIMATION

An approach to calculating ϵ_c, which combines an account of band structure and scattering with the merit of being simple, is based on quasi-classical Boltzmann transport equation. This is restricted by the requirement that the radiation quantum is much smaller than the mean electron energy: $\hbar\omega \ll \langle E \rangle$. In the relaxation-time approximation, the Boltzmann equation can be solved in a closed form for an arbitrary band spectrum $E(\mathbf{k})$. This gives in Eq. (4)

$$\epsilon_c = -\frac{4\pi e^2 N}{\omega}\langle(\omega + i\tau^{-1})^{-1}\mathbf{m}^{-1}\rangle. \tag{12}$$

Here, N is the carrier concentration, τ and $\mathbf{m}$ are the energy-dependent relaxation time and effective-mass tensors, respectively, $\langle ... \rangle$ denotes average over energies E with normalized-to-unity weight $-\frac{\partial f(E)}{\partial E}\cdot\frac{N(E)}{N}$, where $N(E)$ is the number of band states with energies less than E, and f is the Fermi-Dirac distribution. The conduction band in silicon has six equivalent minima (valleys) in the Γ-X directions. Constant-energy surfaces are those of revolution, so $\mathbf{m}$ has two principal values $m_\parallel$ and $m_\perp$. Near the minima ($E < 0.15$ eV), they are constant: $m_\parallel \approx 0.98m_0$, $m_\perp \approx 0.19m_0$, and the constant-energy surfaces are ellipsoids. At larger E's, the masses (mostly $m_\perp$) increase with increasing E, and the ellipsoids become warped [15]. The tensor τ has the same principal axes as $\mathbf{m}$, with principal values $\tau_\parallel$ and $\tau_\perp$. Deformation acoustic (DA)-phonon scattering is nearly isotropic ($\tau_\parallel \approx \tau_\perp$), and deformation optical (DO)-phonon and point-defect scattering are isotropic. For ionized-impurity scattering, tensor τ, introduced as an approximation, is essentially anisotropic.

At $\omega\tau \ll 1$, Eq. (12) gives

$$\epsilon_1 = n_1^2, \quad \epsilon_2 = 2n_1k_1 + n_1^2\frac{\omega_p^2\tau_{dc}}{\omega}, \tag{13}$$

and at $\omega\tau \gg 1$

$$\epsilon_1 = n_1^2(1 - \omega_p^2/\omega^2), \quad \epsilon_2 = 2n_1k_1 + n_1^2\frac{\omega_p^2}{\omega^3\tau_{ac}}. \tag{14}$$

In Eqs. (13, 14) ω_p is the electron plasma frequency defined by

$$\omega_p = \frac{1}{n_1}\sqrt{\frac{4\pi e^2 N}{m_c}}, \quad \frac{1}{m_c} = \langle\frac{1}{3m_\parallel} + \frac{2}{3m_\perp}\rangle, \tag{15}$$

τ_{dc} and $1/\tau_{ac}$ are the combined energy-valley averages of the tensor τ, and the tensor inverse to τ, respectively:

$$\tau_{dc} = m_c \left\langle \frac{\tau_\parallel}{3m_\parallel} + \frac{2\tau_\perp}{3m_\perp} \right\rangle, \tag{16}$$

$$\frac{1}{\tau_{ac}} = m_c \left\langle \frac{1}{3m_\parallel \tau_\parallel} + \frac{2}{3m_\perp \tau_\perp} \right\rangle. \tag{17}$$

The quantity m_c is called *optical* or *conductivity effective mass.* With the use of cyclotron-resonance data, the average in Eq. (15) is calculated trivially to give $m_c = 0.26m_0$.

If, for some reasons, τ_{dc} and τ_{ac} are close to each other, the two limits Eq. (13) and Eq. (14) may be interpolated by the simple formula

$$\epsilon = \epsilon_1 - \frac{n_1^2 \omega_p^2}{\omega(\omega + i\gamma)}, \quad \gamma = \frac{1}{\tau}, \tag{18}$$

which is the celebrated Drude (also Drude-Lorentz or Drude-Zener) equation, and τ is the relaxation time [8, 9, 16]. For isotropic τ, the closeness of τ_{dc} and τ_{ac} is certainly realized when carriers are degenerate. In n-Si with the valley density-of-state effective mass $m_d = m_\parallel^{1/3} m_\perp^{2/3} \approx 0.33m_0$, no degeneracy occurs unless $N \geq 10^{20}$ cm^{-3}.

In order to validate the Drude equation at all concentrations, the relation $\tau_{dc}/\tau_{ac} = 1.13$, valid for combined DA-phonon and point-defect scattering in non-degenerate statistics, is used. For ionized-impurity scattering another reason must be sought, because $\tau_{dc}/\tau_{ac} \gg 1$ even in the isotropic band. At heavy doping, the allowance of Eq. (18) implies the existence of a mechanism which 'binds' one-particle currents into collective variable, total current, which relaxes as a whole. This mechanism could be electron-electron (*e-e*) interaction, which smears an individual electron momentum but conserves the total one. Then the response of the electron plasma on an external EM field will be described in terms of total momentum, provided that the electron momentum exchange in *e-e* collisions becomes faster than the electron momentum relaxation due other mechanisms, as N increases over some value. However, this picture is only partially adequate because the *e-e* momentum-relaxation rate is of the same order of magnitude as that due to ionized impurities, though detailed estimates are not widely known especially for the anisotropic band.

IV FREE-CARRIER CONTRIBUTION TO THE DIELECTRIC FUNCTION IN QUANTUM ABSORPTION REGIME: GENERALIZED DRUDE APPROACH

The Boltzmann equation becomes invalid at $\hbar\omega > \langle E \rangle$, since in this case radiation influences the scattering process. In the quantum regime, the act of

scattering is a transition between initial state with momentum $\mathbf{k}$ and energy $E(\mathbf{k})$ and final state with momentum $\mathbf{k}'$ and energy $E(\mathbf{k}')$ with radiation quanta absorbed or emitted: $E(\mathbf{k}') = E(\mathbf{k}) \pm \hbar\omega$. In the quantum regime, ϵ_c was calculated in the terms of transition probabilities using time-dependent perturbation theory. The first calculations of this type were reported 40 years ago by Fan *et al.* in connection with the first IR-absorption measurements on Ge [17] and Si [18]. For DA-phonon scattering, the absorption coefficient (Eq.(10)) obeys a power law: $n\alpha \propto \omega^{-1.5} \propto \lambda^{1.5}$ at $\hbar\omega > \langle E \rangle$. At $\langle E \rangle/\hbar > \omega > 1/\tau$, quantum theory gives the same result as semiclassical theory or the Drude approximation at $\omega\tau > 1$ (Eqs. (14, 18) with Eqs. (2, 10))

$$n\alpha \approx \frac{n_1^2}{c\tau}\left(\frac{\omega_p}{\omega}\right)^2 \propto \lambda^2. \tag{19}$$

DO-phonon scattering in n-Ge was also considered by Fan *et al.* [17]; phonon-assisted absorption in a many-valley conduction band was studied by Meyer [19] and Rosenberg and Lax [20]. The method was recapitulated by Dumke [21] in 1960. Ionized impurity-assisted absorption in the Born approximation was studied by Meyer [19] and Rosenberg and Lax [20], and with Coulomb wave functions by Visvanathan [22] and Donovan [23]. It was found that in the quantum regime, $n\alpha \propto \omega^{-3.5} \propto \lambda^{3.5}$. The transition to Eq. (19) may not occur even after $\langle E \rangle$ exceeds $\hbar\omega$. The reason is, though the electron wave packet as a whole starts to move at thermal equilibrium, its breadth δr is still determined by the oscillations in radiation field: $\delta r = \sqrt{\hbar/2m^*\omega}$, m^* being an effective mass. So at $\delta r < r_s$ (screening length) the electrons 'feel' an unscreened impurity for which $n\alpha \propto \omega^{-3} \propto \lambda^3$ in the classical frequency region [22, 23], and the limit of Eq. (19) is reached only at $\delta r > r_s$. The calculations using transition probabilities require throwbacks to first principles, and are recast each time a new mechanism is considered. From the late 1960s to 1970s, studies devoted to the derivation of generalized Boltzmann equations, which could recover both quantum and classical regimes, were carried out. Having no room to review this subject here, we refer to the contribution of Jensen [24]. Note that at $\omega\tau \gg 1$, the quantum Boltzmann equation and the transition-probability methods give close results.

Kubo quantum-admittance formalism [25] with second quantization allowed researchers to automate the calculations at high frequencies in a reasonably correct, unified form. The Kubo formula for dynamical conductivity [25] reads

$$\sigma(\omega) = \int_0^\infty \exp(i\omega t) \int_0^{1/kT} \langle J_x(t - i\hbar s) J_x(0) \rangle_T \, dt ds. \tag{20}$$

Here, J_x is x −(or any) component of electric-current operator,

$$A(t) = \exp(it\mathcal{H}/\hbar) A \exp(-it\mathcal{H}/\hbar), \tag{21}$$

where $\mathscr{H}$ is a Hamiltonian, and $\langle ... \rangle_T$ stands for thermodynamic average with the temperature T. Using integration by parts with respect to time t, in Eq. (20) the free-carrier contribution (Eq. (4)) can be identically transformed to

$$\epsilon_c = -\frac{\Omega_p^2}{\omega^2}\left[1 + \frac{\Pi(\omega)}{i\omega}\right], \quad \Omega_p^2 = 4\pi \int_0^{1/kT} \langle J_x(i\hbar s) J_x(0)\rangle_T \, ds \tag{22}$$

with

$$\Pi(\omega) = 4\pi\Omega_p^{-2} \int_0^\infty \exp(i\omega t) \int_0^{1/kT} \langle \dot{J}_x(t + i\hbar s)\dot{J}_x(0)\rangle_T \, dtds, \tag{23}$$

where the upper dot denotes the time derivative:

$$\dot{A}(t) = \frac{i}{\hbar}[\mathscr{H}, A(t)].$$

Eq. (23) is convenient for the calculation at high frequencies. Indeed, $\Pi(\omega)$ is at least of *second order* with respect to the interactions, since the electric-current operator commutes with the kinetic energy part of $\mathscr{H}$. Thus, at $\omega\tau \gg 1$ the interactions can be neglected when considering the correlation function in Eq. (23). Then the lowest-order estimate of Eq. (23) $\Pi^{(2)}(\omega) = \Gamma(\omega)$ is obtained in a closed form as a sum of the contributions of different scattering mechanisms. It is expedient to note that in this approximation, the *e-e* interaction does not contribute to $\Gamma(\omega)$ for the isotropic band, where J_x is proportional to the total momentum.

With $\Pi(\omega)$ replaced by $\Gamma(\omega)$, Eq. (22) becomes a fragment of the high-frequency expansion of

$$\epsilon_c = -\frac{\Omega_p^2}{\omega[\omega + i\Gamma(\omega)]}. \tag{24}$$

The extention of Eq. (24) to all ω's is called the *generalized Drude approximation* (GDA). The structure of this type may formally be obtained from exact Eq.(22) using the Mori projection ansatz [26]. Of course, the prescription of the structure by no means validates GDA. The validity of GDA in the whole frequency range was extensively discussed by Sernelius [27]. It was applied to simple metals [28], and to an isotropic model of doped n-Si [29, 30]. GDA appears to be a good approximation if the *e-e* collisions dominate, as outlined in Section III.

Since $\Omega_p = n_1\omega_p$ in the leading approximation, the total DF (Eq. (10)) in GDA differs from the Drude formula (Eq. (19)) only in the presence of the relaxation-memory function $\Gamma(\omega)$ *instead of constant relaxation rate* γ. If the valleys are uncoupled, GDA must be applied separately to each valley. The calculations for the valleys of $\langle 100\rangle$, and $\langle 010\rangle$, $\langle 001\rangle$ types give, in

general, two different contributions $\Gamma_{\parallel}(\omega)$, and $\Gamma_{\perp}(\omega)$, respectively. The total DF in this case is

$$\epsilon = \epsilon_1 - \frac{4\pi Ne^2}{3m_{\parallel}\omega[\omega + i\Gamma_{\parallel}(\omega)]} - \frac{8\pi Ne^2}{3m_{\perp}\omega[\omega + i\Gamma_{\perp}(\omega)]}. \tag{25}$$

At the high-frequency limit only the average relaxation function

$$\Gamma(\omega) = \frac{m_c}{3}\left[\frac{\Gamma_{\parallel}(\omega)}{m_{\parallel}} + 2\frac{\Gamma_{\perp}(\omega)}{m_{\perp}}\right] \tag{26}$$

enters Eq. (25), thus comprising the first term of exact perturbation expansion as required. In the presence of a scattering, that couples the valleys, Eq. (25) must be changed (Eq. (3.8) [27]).

V EXPERIMENTAL DATA OVERVIEW

There exists a body of literature on the optical properties of variously doped n-Si crystals in the IR. The equilibrium solubility of atoms of As, P, and Sb in Si does not exceed $5 \times 10^{20}\text{cm}^{-3}$ [31]. The use of advanced ion-implantation technology increased the active dopant density far above this (up to 5×10^{21} cm^{-3}) and allowed plasma effects to be observed in the near IR [32–34].

Basically, these studies used reflection and/or transmission measurements. For bulk-doped samples at $N < 10^{19}\text{cm}^{-3}$, it is technologically possible to prepare slabs suitable for transmission measurements. With the use of Eqs. (6–10), optical constants are retrieved from measured values of R_a and T_a. As is seen from Eq. (14), extrapolating measured ϵ_1 to zero from the region $n \gg k$ gives the plasma frequency, and hence the optical effective mass m_c. Using this method, Spitzer and Fan [18] found $m_c = 0.27m_0$ for $N = 3.6 \times 10^{18}$ cm^{-3}, in excellent agreement with the value cited in Section II. It was pointed out by Fistul [31] that for heavier doping, the method has low reliability, as was seen from the result $m_c = 0.44m_0$ of Cardona *et al.* for $N = 6.5 \times 10^{19}$ and 1.1×10^{20} cm^{-3} [35]. At doping in excess of 10^{19} cm^{-3}, reflectometry was mostly used [33, 36–39]. A comprehensive study of reflection was made by Howarth and Gilbert [36], who measured 16 n-Si samples doped in the range $7.4 \times 10^{18}\text{cm}^{-3} - 1.67 \times 10^{20}\text{cm}^{-3}$. For ion-implanted n-Si layers, combined measurements of reflection and transmission were carried out by Streltsov and Titov [40], Miyao *et al.* [32], and Aspnes *et al.* [34].

Two approaches to processing reflectivity data of bulk-doped samples were used. The first one, which relied on the Drude model, was proposed by

Kukharski and Subashiev [38], and advocated by Lambert [41]. In this approach, ω_p and γ are found from the reflectivity minimum frequency, ω_{min} (wavelength λ_{min}), and the value of reflectivity minimum, R_{min}. With known ω_p, one can calculate m_c if N is measured and vice versa; this method is an improvement of widely used approximations: $(n-1)^2 \gg k^2$ or $n \sim 1$, $k \sim 0$ [17, 18, 35–37]. The method of Kukharski and Subashiev [38] was used also for doped n-Si layers in a homogeneous approximation [40] and modified by Slaoui and Siffert [33] for concentration profiles. The second approach is KKA giving n and k independently of the physical model (see Section II). However, as a rule, the retrieved n and k were not displayed, and again, the Drude model was used. Spitzer *et al.* [37] assumed $m_c = 0.28m_0$ and studied the influence of heat treatment on γ in a sample with $N = 7.5 \times 10^{19}$ cm^{-3}. Barta [39] expressed m_c and τ via ϵ_1 and ϵ_2, which were known after KKA (see Eqs. (1, 2)). The parameters were calculated at the zero of ϵ_1, which gave: $m_c = 0.31m_0$ and $m_c = 0.35m_0$ for two samples with $N = 9 \times 10^{19}$ cm^{-3} and 1.6×10^{20} cm^{-3}, respectively, and about the same value of the relaxation parameter $\gamma \sim 1.09 \times 10^{14}$ s^{-1} for both samples.

A variety of spectra of the absorption coefficient α was observed in n-Si. Dubrovsky in his thesis cited by Fistul [31] in the range of $N \sim (0.1 - 1) \times 10^{20} cm^{-3}$ and reported the dependence $\alpha \propto \lambda^{3.5}$, which is characteristic for ionized-impurity scattering (see Section IV). Balkanski *et al.* [42] measured $\alpha \propto \lambda^2$ at $4\mu m < \lambda < 6\mu m$ in bulk-doped samples with $N = 6 \times 10^{18}$, 10^{19} cm^{-3}. On the contrary, in ion-implanted layers with $N \sim (0.5 - 2) \times 10^{20} cm^{-3}$, the dependence $\alpha \propto \lambda^{1.5}$ was observed at $2\mu m < \lambda < 10\mu m$ [40]. Later this was also observed in laser-annealed poly-Si layers with a much larger concentration [34]. Based on the fact that this dependence is obtained for DA-phonon scattering (see Section VI), Streltsov and Titov [40] asserted that the phonon mechanism dominates the scattering processes in n-Si doped in excess of 10^{19} cm^{-3}.

On the one hand, the researchers were disposed to retrieve some physical information rather than tabulate optical constants. On the other hand, such restricted information can hardly be used in practice. For a fast and accurate approximation of optical constants in a wide range of N and ω, Humlíček and Wojtechovsky [43] proposed a KKA-adjusted Drude model for a best fit of reflectivity data. Using the data for the samples of Howarth and Gilbert [36] and three of their own [43], they found fitting values of ω_p and γ for each, and derived linear relations:

$$\begin{aligned} \gamma &= 113 + 0.208\ \omega_p \quad \text{(Si: Sb)}, \\ \gamma &= 153 + 0.265\ \omega_p \quad \text{(Si: As)}, \\ \gamma &= 194 + 0.174\ \omega_p \quad \text{(Si: P)}, \end{aligned} \tag{27}$$

where ω_p and γ are in units cm^{-1}, and $N \geq 5 \times 10^{18}$ cm^{-3}. The authors sought a dependence between m_c, as calculated using the definition of ω_p,

and N. Due to a large scatter, the result (Eq. (15) [43]) seemed so unphysical that they recommended substituting the value $m_c = 0.26m_0$ for interpolation of optical constants using Eq. (27). Thus, at $N \leq 10^{20}$ cm^{-3} it can be put in the Drude equation (Eq. (18)):

$$n_l^2\omega_p^2 = 3.452 \times 10^{-13} N\,\mathrm{cm}^{-2}, \tag{28}$$

where N is in units cm^{-3}.

Eq. (28) can be validated by fittting ω_p of Humlíček and Wojtechovsky [43] linearly to N. The result is shown in Fig. 1. We display only the fit for Si: As, which yields $m_c = 0.27m_0$. It fits the data reasonably well up to $\sim 8 \times 10^{19}$ cm^{-3}. The data for Si: Sb also have a small scatter and are fitted with $m_c = 0.28m_0$. The data for Si: P have larger scatter especially at the end concentrations. The linear fit using the data for $N \leq 10^{20}$ cm^{-3} gives $m_c = 0.29m_0$. The point $N = 1.67 \times 10^{20}$ cm^{-3} (not shown in Fig. 1) drops drastically below this fit. Including this point in the fit increases the value of m_c to $0.31m_0$; the calculation using only this point gives $m_c = 0.34m_0$, which are about the same as obtained by Barta [39]. Since m_c must be independent of impurity type, we conclude that its apparent increase at $N \leq 10^{20}$ cm^{-3} is a result of experimental uncertainty. This agrees with band-structure calculations of van Driel [15], which predicted different behavior of m_c: near-to-constant $m_c = (0.26 - 0.27)\ m_0$ at $N \leq 10^{20}$ cm^{-3}, and monotonic in-

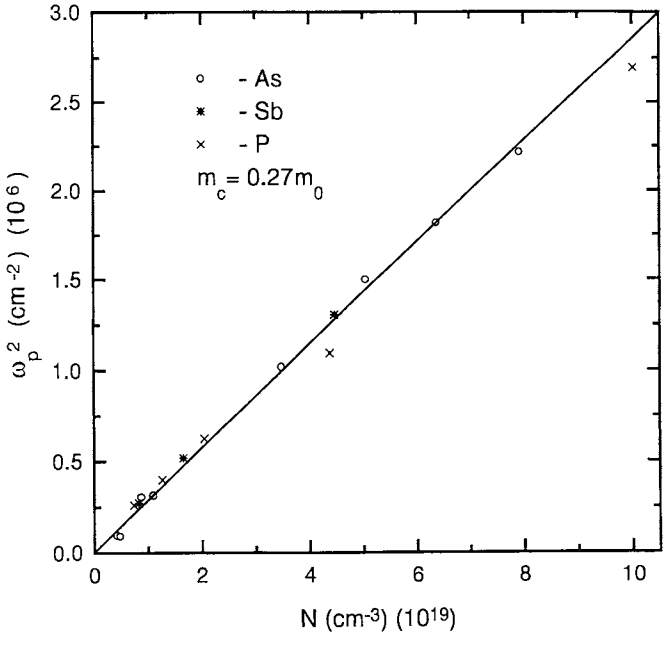

Fig. 1. Plasma frequency squared versus electron concentration for various doped n-Si. Si: As (o), Si: Sb (*), Si: P (×). Straight line is the best linear fit for Si: As giving $m_c = 0.27m_0$.

crease at $N > 10^{20}$ cm^{-3} to about $0.57m_0$ at 5×10^{21} cm^{-3}. This huge increase of m_c was observed in ion-implanted samples [32–34], whereas its onset is seen in the last two Si: P samples of Howarth and Gilbert [36]. As seen from Fig. 2, the agreement of theory [15] and experiment [32–34] is fair.

To derive a fit for γ at $N < 5 \times 10^{18}$ cm^{-3}, the transmission through four samples with $N = 1.4 \times 10^{16}$, 7.5×10^{16}, 10^{17}, and 1.15×10^{17} cm^{-3} was measured by Humlíček and Wojtechovsky [43]. It was found that there is a good agreement between the retrieved γ's and the inverse relaxation times extracted from the mobility data. Using a simplified empirical fit for the mobility, the authors obtained

$$\gamma = 35910 \frac{1 + (10^{-16} N/9.68)^{0.68}}{1427 + 52.2\,(10^{-16} N/9.68)^{0.68}} \text{ cm}^{-1}, \tag{29}$$

where, as usual, N is in units cm^{-3}. Even though optical data between 1.2×10^{17} cm^{-3} and 3.6×10^{18} cm^{-3} are missing, and the mobility data are uncertain, the γ values obtained from Eq. (29) and Eq. (27) match reasonably at $N = 5 \times 10^{18}$ cm^{-3}. To summarize, Eq. (18) (ω in units of cm^{-1}) with Eq. (28) and empirically adjusted relaxation parameter given by Eq. (29)

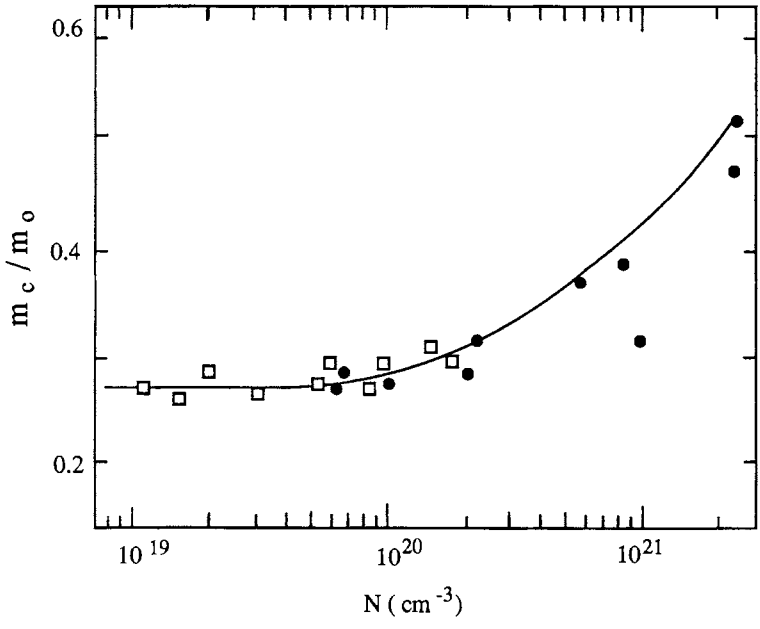

Fig. 2. Dependence of optical effective mass in n-Si on free-carrier concentration. The solid line represents theoretical curve after van Driel [15]. Open squares and solid circles are experimental data after Howarth and Gilbert [36] (□) and Miyao *et al.* [32] (●). Reprinted with permission.

or Eq. (27), can be used for modelling the optical constants in n-Si versus both wavenumber and electron concentration. At light doping, spectral variation of ϵ_l in Eq. (18) is to be taken into account. For this purpose, the real part of ϵ_l can be modeled using the known Sellmeier-type formula [12], and the imaginary part can be taken from the tables [12, 13]. At doping levels well above 10^{19} cm^{-3} the relaxation time τ retrieved from experimental data of Miyao *et al.* [32] and Slaoui and Siffert [33] is smoothly decreasing with the increase of N and then saturated to 3×10^{-15} s near $N = 5 \times 10^{21}$ cm^{-3} as shown in Fig. 3.

It is worthwhile to mention that the reflectivity data are affected by the state of the sample's surface. For example, Spitzer *et al.* [37] noted that for surfaces specially polished or etched, $R_{min} \sim 0.11$, whereas with standard polishing technique, values lower than 0.139 did not occur [36, 37]. Moreover, heat treatment, without affecting λ_{min}, lowered R_{min} to 0.067 [37]. An analysis of this reflectivity curve indicated that relaxation time must depend on λ [37].

VI GENERALIZED DRUDE APPROXIMATION FOR n-Si

In this section we consider all the necessary ingredients for the application of GDA to n-Si. This is done to point out that the results of this treat-

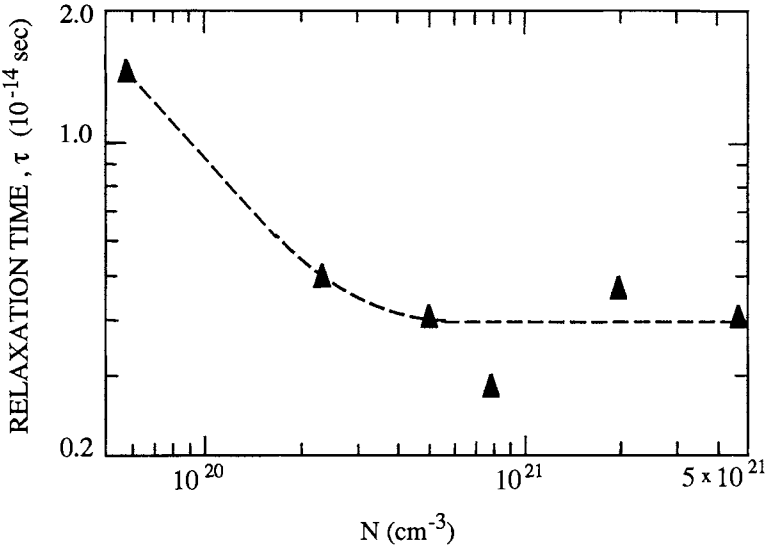

Fig. 3. Dependence of relaxation time τ, which enters the Drude Eq. (18), on free-carrier concentration in ion-implanted n-Si. Solid triangles are experimental data after Miyao *et al.* [32]; dashed line is a guide for the eye. Reprinted with permission.

ment conflict with the Drude approximation, since screened-impurity-potential models lead to a strong spectral dependence of the relaxation functions. In turn, the allowance of a constant τ contradicts some experimental data at short wavelengths [31, 34, 41], and, though less certainly, near λ_{min} [37]. Ideally, one might hope that for a much-studied material like n-Si, the theory and experiment would agree. In reality, poor knowledge of impurity potentials in heavily doped n-Si (see below), as well as the uncertainties of experimental data, make disagreement quite possible. Let us first consider the contributions to the relaxation functions existing in n-Si.

Electron-Phonon Scattering A

Electron-phonon scattering dominates in lightly doped n-Si. The actual mechanisms are DA-phonon and intervalley-phonon scattering. Unlike n-Ge, in n-Si, DO-phonon scattering is not allowed [44]. There are two types of intervalley scattering. In the first, *g*-type, an electron is transferred from a given valley to a valley with the same orientation, and in the second, *f*-type, to one of the four valleys with a different orientation. The *g*-transition uses an LO-phonon with wavevector at the point Δ and energy $\hbar\omega_{LO} \approx 735$K. Two *f*-transitions are assisted by the two phonons with wavevector at the point S: TO ($\hbar\omega_{TO} \approx 690$K) and LA ($\hbar\omega_{LA} \approx 510$K). Matrix elements of these transitions are unknown, but fortunately DA-phonon scattering more or less accounts for room-temperature mobility in lightly doped n-Si ($\mu_{300} \approx 1350$ cm^2 V^{-1}s^{-1}, the mobility relaxation time $\tau_0 \approx 2.00 \times 10^{-13}$ s). The intervalley processes contribute negligibly at room temperature because the corresponding phonon occupation numbers are rather small.

For DA-phonon scattering Eq. (23), neglecting weak anisotropy factors, gives:

$$\Gamma_{\upsilon}^{(ep)}(\omega) = \frac{\Gamma_{DA}}{F_{1/2}(\eta)} \int_0^{\infty} \frac{x}{\bar{\omega}} \ln\left[\frac{1 + \exp(\eta - x - \bar{\omega}^2/16x + \bar{\omega}/2)}{1 + \exp(\eta - x - \bar{\omega}^2/16x - \bar{\omega}/2)}\right] dx, \qquad \upsilon = \parallel, \perp, \quad (30)$$

where $\bar{\omega} = \hbar\omega/kT$, $\eta = \zeta/kT$ is the reduced chemical potential, $F_r(\eta)$ are the Fermi integrals,

$$\Gamma_{DA} = \frac{4\Xi_u^2}{3\hbar\rho u_l^2}\left(\frac{2m_d kT}{\pi\hbar^2}\right)^{3/2}, \quad (31)$$

where Ξ_u is shear-deformation potential, ρ is the crystal density, and u_l is the longitudinal sound velocity. With known values of $\Xi_u \approx 9.6$ eV, the band

and lattice parameters, one obtains $\Gamma_{DA} \approx 0.566 \times 10^{13}\ s^{-1}$ at $T = 300K$. In the non-degenerate case, one obtains

$$\Gamma^{(ep)}(\omega) = \Gamma_{DA}\left(\frac{\overline{\omega}}{4}\right)\sinh\left(\frac{\overline{\omega}}{2}\right)K_2\left(\frac{\overline{\omega}}{2}\right), \tag{32}$$

where $K_2(x)$ is the McDonald function. At $\overline{\omega}/\max(\eta,1) \gg 1$, Eq.(30) gives the asymptotic form of the absorption coefficient (see Section IV):

$$n\alpha^{(ep)} \approx \frac{16Ne^2}{9c\tau m_c\omega^2}\left(\frac{\pi\hbar\omega}{kT}\right)^{1/2}, \quad \tau = \tau_0 \exp(-\eta)F_{1/2}(\eta), \tag{33}$$

where τ_0 is DA-phonon mobility relaxation time for light doping. In Streltsov and Titov [40] the absorption spectra retrieved from the transmission data for ion-implanted Si: P layers with $N = (0.5 - 2) \times 10^{20}\ cm^{-3}$ were shown to fit Eq. (33). Using qualitative arguments, the authors stated that ionized-impurity scattering should 'switch-off' in the spectral interval under study, so observed absorption is due to acoustic phonons; the same conclusion was also drawn by Aspnes *et al.* [34]. At $N = 10^{20}\ cm^{-3}$ the fit by Streltsov and Titov [40] needed τ about 15 times smaller than τ_0, and the formula in Eq. (33) gives a factor ~ 3. The rest, however, is *not necessary* due to the increase of electron-phonon interaction as was claimed by Streltsov and Titov [40]. Actually, any short-range interaction leads to the same spectral dependence as given by Eq. (33), but with another τ_0. It might be the short-range part of electron-donor interaction (see next subsection). In this case, the asymptotic form in Eq. (33) is almost *independent* of T, whereas in the case of phonons, it is *linear* with respect to the temperature. Thus, the origin of $\lambda^{1.5}$-absorption spectrum can not be identified until its temperature dependence is studied experimentally. More seriously, the concept of Aspnes *et al.* [34] and Streltsov and Titov [40] implies impurity scattering *to play no role* also at DC. Indeed, the fit values of τ attributed by Streltsov and Titov [40] *solely* to electron-phonon interaction correspond to the mobilities in the range (61–88) $cm^2\ V^{-1}s^{-1}$, typical for the *measured* mobility at the studied concentrations.

B Electron-Impurity Scattering

A key problem in the theoretical description of electron-donor scattering is to determine the electron-donor interaction potential. Usually it is taken in the form of screened Coulomb potential

$$V_i(\mathbf{r}) = -\frac{e\exp(-|\mathbf{r} - \mathbf{R}_D|/r_s)}{\epsilon_l|\mathbf{r} - \mathbf{R}_D|}, \tag{34}$$

where e is the electron charge, $\mathbf{R}_D$ is a donor position, and r_s is a screening length. The lowest-order calculation of Eq. (23) with respect to this potential can be performed easily no matter what model for r_s is chosen. In the Debye-Thomas-Fermi model and isotropic valleys, the calculation was carried out in our paper [29]. In a theory that seems more consistent, the screening is not introduced but is *derived* in perturbative electron-gas calculations, electron-impurity, and *e-e* interactions being treated simultaneously. For many-valley bands such a calculation of Eq. (23) was performed by Sernelius [27] using a diagrammatic method. His result for the impurity contribution can be transformed to:

$$\Gamma_v^{(ei)}(\omega) = \frac{6e^2}{m_d\omega}\mathrm{Im}\int\frac{d^3q}{(2\pi)^3}q^2 a_\nu(\mathbf{q})V_i(\mathbf{q};\omega)V_i(\mathbf{q},0)[\chi_0(q,\omega) - \chi_0(q,0)], \quad (35)$$

where $a_\parallel(\mathbf{q}) = \cos^2\theta$, $a_\perp(\mathbf{q}) = 1/2\ \sin^2\theta$, $\chi_0(q,\omega)$ is the wavevector-frequency-dependent electron polarizability in one parabolic valley (Lindhard function) with effective mass m_d;

$$V_i(\mathbf{q},\omega) = \frac{-4\pi e}{\epsilon_l q^2\left(\dfrac{m_\parallel a_\parallel}{m_d} + \dfrac{m_\perp a_\perp}{m_d}\right) + 8\pi e^2\sum\limits_{k=1}^{3}\chi_0(q_k,\omega)} \quad (36)$$

is the space-time Fourier transform of the effective interaction potential, where: $q_1 = q$, $q_2 = qK^{1/2}\,[\cos^2\theta + K^{-1}(\cos^2\varphi + K^{-1}\sin^2\varphi)]^{1/2}$, $q_3 = qK^{1/2}\,[\cos^2\theta + K^{-1}(\sin^2\varphi + K^{-1}\cos^2\varphi)]^{1/2}$, $K = m_\parallel/m_\perp$, θ and φ being the polar and azimuthal angles, respectively. In the isotropic valleys Eq. (35) reduces to our result [29] by putting $\omega = 0$, $q = 0$ in the polarizability term of Eq. (36), that is also obtained using transition-probability method. Sernelius [27] obtained an expression for an *e-e* contribution that describes 'friction' damping of relative momentum of differently oriented valleys. It changes the structure of Eq. (25) at general ω, but at high frequencies contributes only an additive term to Eq. (26).

Both screening models take into consideration only the long-range part of electron-donor interaction potential. For uncompensated n-Si at $T = 300$K, because of full donor ionization, they predict independence of the scattering rate from impurity type. At the same time, there exists experimental evidence of such dependence for the mobility [31] and for IR reflectance [34] (see Section III). The dependence is probably due to a short-range potential, for which at least two sources can be pointed out. The first is the difference between the atomic potentials of Si and the donor atom, which is responsible for the deviation of dopant ionization energy from the Bohr energy, and for the difference in those for different dopants. These substitution potentials for the three dopants in Si were estimated by Viña and Cardona [11]. The second is a local deformation in the vicinity of the impurity that affects the valleys through the deformation potential the same way as the lattice

vibrations do. We have not found a reliable estimation of this effect in the literature. The near-IR absorption spectra [34, 40] offer an additional evidence that a short-range potential emerges with doping (see Subsection VIA).

The calculation of DC mobility is a crucial test for the model, because without agreeement between theory and experiment at DC, the disagreement will appear also in the IR. As is well known, the mobility calculated in the Born approximation with respect to the Debye-Thomas-Fermi potential, and isotropic-valley approximation (Brooks-Herring mobility) disagrees strongly with experimental data [45]. The calculations in GDA with (q, ω)-screening model (Eqs. (25, 35, 36)) include triple integration of complicated function with respect to q, θ, φ. This is a formidable task for desktop-computer simulations (a Cray-type supercomputer was used by Serrelius [27]). In our case $K^{1/2} \approx 2.27$, the mean values of $q_{2,3}$ appear to be close to q, so we could put $q_{2,3} = q$ in Eq. (35), but retain angular dependence through the functions $a_\nu(\mathbf{q})$. After this, the angle integration is carried out analytically. The relaxation functions are expressed via the integrals with respect to the reduced-energy variable x as in Eq. (30), but with much more complicated integrands. Despite this complexity, they still allow a fast desktop-computer calculation. The calculations become much faster in the Debye-Thomas-Fermi limit.

Neglecting e-e scattering, the DC relaxation time is found using GDA extrapolated to $\omega = 0$:

$$\tau = \frac{m_c}{3m_\parallel \Gamma_\parallel(0)} + \frac{2m_c}{3m_\perp \Gamma_\perp(0)}. \tag{37}$$

At maximum e-e scattering, τ changes from this value to $\Gamma^{-1}(0)$, where $\Gamma(\omega)$ is given by Eq. (26) [27]. We calculated τ for $N = 10^{17}$, 10^{18}, 10^{19}, and 10^{20} cm^{-3} and obtained: $\tau = 1.31 \times 10^{-13}$, $(7.22\text{–}7.07) \times 10^{-14}$, $(3.90\text{–}3.77) \times 10^{-14}$, and $(2.58\text{–}2.51) \times 10^{-14}$ s, respectively. The second value in the brackets shows the effect of e-e scattering, which thus proves to be small. Corresponding 'experimental' values of τ calculated using Eqs. (27–29) are: 1.08×10^{-13}, 4.22×10^{-14}, $(1.83\text{–}1.69) \times 10^{-14}$, and $(1.09\text{–}1.02) \times 10^{-14}$ s, respectively. In the last two data, the first value corresponds to Si: P and the second to Si: As; close values are extracted from the Irvin resistivity curves [46]. We see systematic discrepancy between the theoretical and experimental values of τ by a factor which increases with the increase of N from ~ 1.2 to $\sim 2.3 - 2.5$. The Debye-Thomas-Fermi model gives a larger factor (3.5–3.7 at $N = 10^{20}$ cm^{-3}). To the best of our knowledge this discrepancy has not yet been resolved, and is still discussed in the literature [47]. Thus, the disagreement between optical constants calculated by GDA using the screening models and those calculated using the empirically adjusted Drude approach [43], arises even if the static values of the relaxation functions are substituted into Eq. (25). Including full frequency de-

pendence does not make the situation better. Moreover, as seen from Fig. 4, the relaxation functions appear to strongly decrease with decreasing λ, so their values at short wavelengths are too small to account for observed absorption. In addition, at heavy doping ($N > 3 \times 10^{18}$ cm^{-3}) the relaxation functions acquire peaks near the plasma wavelength, which are more pronounced for $\Gamma_{\perp}$ (see Figs. 4, 5). Mathematically, these peaks arise from the poles of $V_i(\mathbf{q},\omega)$ in the complex (q,ω)-plane. Physically, they display the response of plasma waves excited by scattered electrons in the screening electron cloud, a feature that cannot appear in the Debye-Thomas-Fermi model. These peaks produce weak humps on the reflectivity curves near λ_{min}, which have never been observed experimentally. In our opinion, this is one more reason to recast the donor potential issue in n-Si.

TABULATION OF OPTICAL CONSTANTS OF DOPED n-Si VII

We tabulated n and k for practical use at nine concentrations in the range from 10^{16} cm^{-3} to 10^{20} cm^{-3}, with roughly a factor-of-three increase for each step, using the fit of Humlíček and Wojtechovsky [43] given by

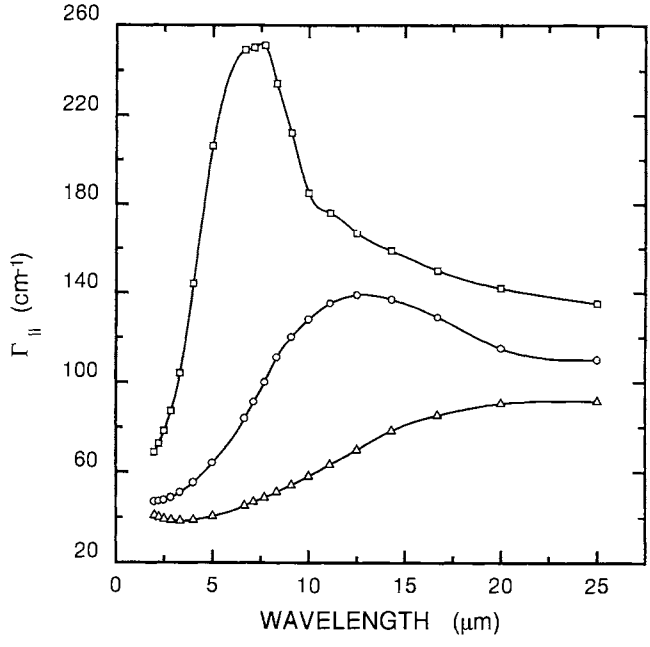

Fig. 4. Theoretical spectra of ⟨100⟩ relaxation function $\Gamma_{\parallel}$ calculated using Eqs. (35, 36) for three electron concentrations: (Δ) $N = 10^{19}$ cm^{-3}; (○) $N = 3 \times 10^{19}$ cm^{-3}; (□) $N = 10^{20}$ cm^{-3}.

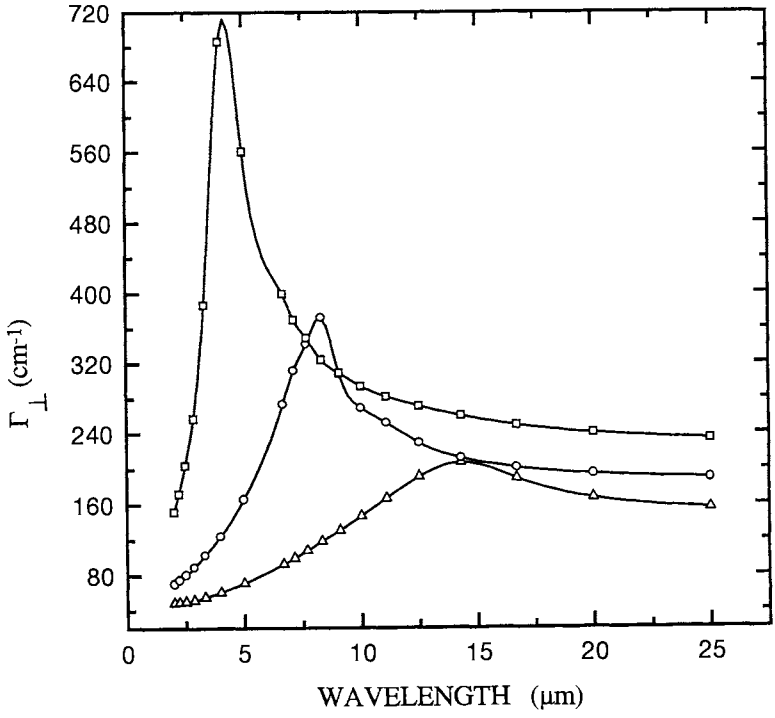

Fig. 5. Theoretical spectra of ⟨010⟩ relaxation function $\Gamma_\perp$ calculated using Eqs. (35, 36) for three electron concentrations: (Δ) $N = 10^{19}$ cm^{-3}; (○) $N = 3 \times 10^{19}$ cm^{-3}; (□) $N = 10^{20}$ cm^{-3}.

Eqs. (27, 28) and Drude Eq. (18). The results are placed in Tables I to IX in the columns headed by abbreviation 'HW'. For heavy doping we display different values for Si: P and Si: As. The fit for Si: Sb (first line of Eq. (27)) was not used because we found that three data points available for this dopant fit a linear function of N better than that of $\sqrt{N}$. Each table covers a spectral interval from 2μm either to 100μm at light and moderate dopings, or to 25μm at heavy doping. The tables can be easily extended to wider intervals using Eqs. (27, 28, 18).

For sake of comparison, in each table we added the columns with theoretical values calculated by us using Eqs. (35, 36) with Eq. (25) as outlined above; they are abbreviated by 'GDA'. It is seen that at light and moderate doping the disagreement between theory and the empirical fit is not so strong. It is more or less concordant with the disagreement at DC discussed above. In some cases, where the fit overestimates γ, theory may be in a better agreement with direct experimental data (see Fig. 6). At heavy doping (Tables VII–IX), the disagreement becomes more drastic especially near the peaks of the relaxation functions. Fig. 7 shows some plots of n and k.

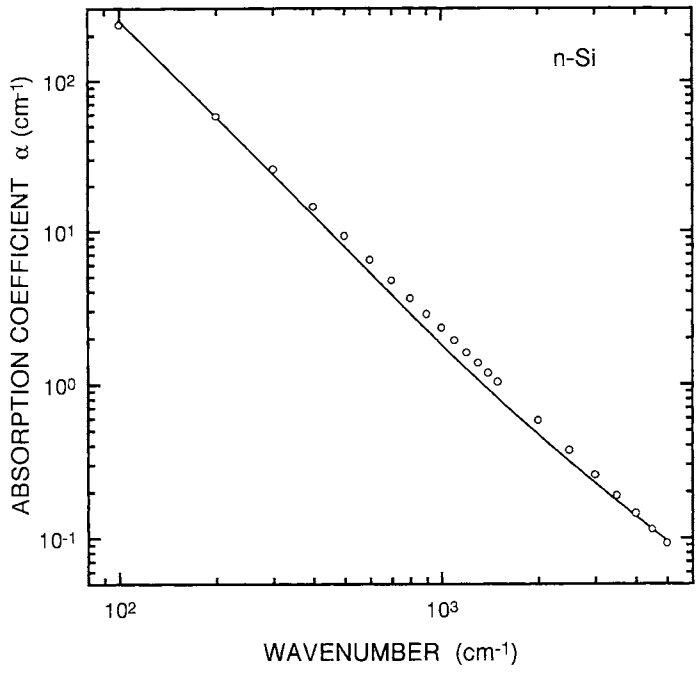

Fig. 6. Absorption spectrum for $N = 10^{17}$ cm^{-3} with lattice absorption extracted. The solid line represents theoretical curve. Open circles are the experimental data for Si: As [43].

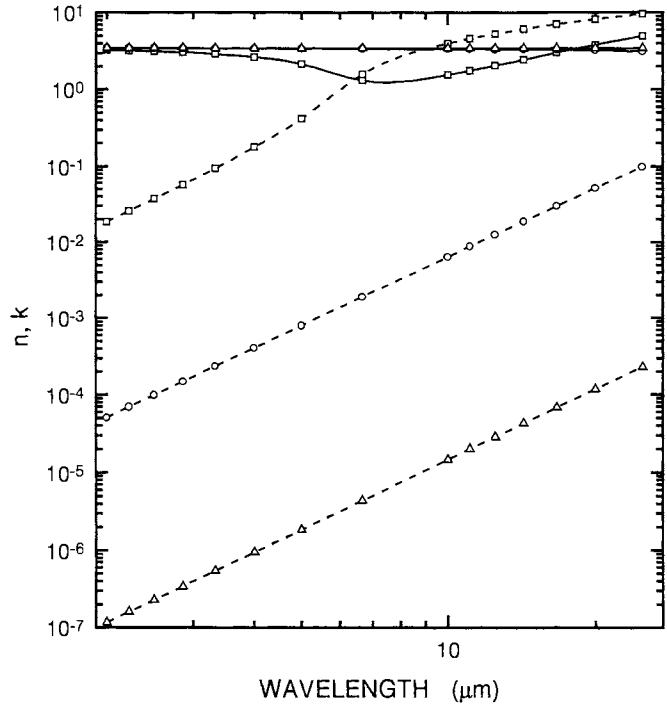

Fig. 7. Log-plot of n and k calculated using Eqs. (18, 27, 29) for three electron concentrations: (Δ) $N = 10^{16}$ cm^{-3}; (○) $N = 10^{18}$ cm^{-3}; (□) $N = 10^{20}$ cm^{-3}. Lines: solid-n, dashed-k. The difference in values of n as well as its spectral variation for (Δ) and (○) are small.

			5.340	3.551	9.048 E 0	1.285 E+1

To conclude, there exists a dicrepancy between theory and experiment for the DF of heavily doped n-Si. This inconsistency is due to an improper model of donor potential, to a much larger extent, than to theoretical shortcomings and experimental uncertainties.

Chapter 7

Optical Parameters for the Materials in *HOC I, HOC II,* and *HOC III*

EDWARD D. PALIK
Institute for Physical Science and Technology
University of Maryland
College Park, Maryland

I. Introduction 187
II. The Parameters 187
References 225

INTRODUCTION I

In *HOC II,* we made an attempt to catalog certain optical parameters for all the materials in *HOC I* and *HOC II.* We have continued this work and present in Table I a listing of Material, Crystal Structure, Symmetry Class (Space Group), Unit-Cell Dimensions, Number of Molecular Units per Unit Cell and Primitive Cell, Number of Optic Modes, Optic Irreducible Representation, Acoustic Irreducible Representation, Transverse and Longitudinal Optic Frequencies (ω_T and ω_L), Plasma Frequency for a Metal ω_p (Drude), Fundamental Band Gap E_g (Direct or Indirect), and dc Dielectric Constant ϵ_o.

THE PARAMETERS II

Usually a cubic metal cannot support a transverse or longitudinal optic mode, and this is indicated with *None.* For a cubic diatomic metal, the LO mode may be degenerate with the TO mode, at least at the zone center. It is not obvious that the LO mode has any oscillator strength, since the free charges can move to cancel any longitudinal planes of charge the lattice tries to set up and maintain. We indicate our doubt with a (?). A dashed (- - -)

This is the first example of a crystal with the same modes both IR and R active. Often, there is not a one-to-one correspondence, presumably because the IR or R intensity is too weak to be measured. Also, some of the high frequency bands may be combination bands.

TABLE g

C graphite [22]

1 $E_{1u}(T)(IR\perp)$	$E_{1u}(L)(IR\perp)$	1 $A_{2u}(T)(IR\parallel)$	$A_{2u}(L)(IR\parallel)$	2 $E_{2g}(R)$	2 $B_{2g}(O)$
1587.0	1587.5	867.8	868.1	42	127
				1575	xx

IR$\perp$ represents electric field E perpendicular to the c axis (ordinary) and IR$\parallel$ represents electric field E parallel to the c axis (extraordinary). This nomenclature will persist until the orthorhombic crystals are reached, whereupon we must revert to $E \parallel a$, $E \parallel b$, $E \parallel c$ notation. For the remaining monoclinic and triclinic unit cells, the situation becomes more complicated because we must choose a Cartesian coordinate system to describe atomic displacement and electric polarization whose x, y, z axes do not line up with all three a, b, c edges of the unit cell.

In most cases, too many lines are seen for each species. Splitting of degenerate modes and combination bands are sometimes invoked to ease this dilemma.

The analyses are incomplete. Note that the modes both IR and R active are shown separately. There is poor correlation between IR, R frequencies. Each IR frequency should have an equal R frequency. Raman experimental arrangement was not described adequately—polarization selection rules, etc. No IR polarization was used to distinguish ∥ and ⊥. Powders in mulls were often used.

For this crystal symmetry $a \approx b \approx c$ and $\beta = 99°29'$. The Cartesian coordinate system is taken as $y \parallel b$, $x \parallel a$, leaving z not quite $\parallel$ to c. Note that for species A_u, atomic displacement is along z, and for B_u, it is along x, y.

It is important to establish the *xyz* Cartesian coordinate system with respect to the *a,b,c* edges of the unit cell and then make the appropriate polarization measurements, E ∥ *a*, E ∥ *b*, E ∥ *c* (not given by group theory), or E ∥ *x*, E ∥ *y*, E ∥ *z* (given by group theory).

line in the ω_p column signifies that a dielectric has no free-carrier plasma frequency, or in a semiconductor the free-carrier plasma is ignored. A dashed (- - -) line in the E_g column signifies there is no fundamental band gap (in a metal or semimetal). An xxx line in the ω_T, ω_L, ω_p, E_g or ϵ_o column signifies that we could not find a value for this parameter in the literature. Hopefully, this will be filled in later.

When the collection of ω_T, ω_L data is large for a given material, the reader is referred to a separate table often containing a reference.

Even though materials like ThF_4 (monoclinic) and Si_3N_4 (hexagonal and trigonal) have very little room-temperature optical data for crystalline forms, they were tabulated in *HOC I* and *HOC II* in polycrystalline or amorphous forms as deposited in thin films for technological applications. The crystalline parameters available are tabulated in Table I. Sometimes there is more than one crystal form of a material at room temperature, but only one form was critiqued. We often include parameters for the other forms in Table I. There are many optical glasses where the primary interest is the visible index of refraction which is controlled by "doping." Fused silica is an example in *HOC I*. We never tabulated *n* for the many optical glasses, but this is done elsewhere [1, 2].

The numbers in Table I have been obtained from several sources including the original reference to the experimental work. It is not practical to cite every reference. Many of the numbers are from several collections and reviews [3–7] and the references therein. In many cases values of ω_T and ω_L from different laboratories vary by ± a few wavenumbers. Values of E_g vary

by ± a very few tenths of an eV. Some modelling and analysis is necessary to determine whether the gap is direct or indirect.

The irreducible representations at the zone center (Γ point) are obtained from the original literature or were calculated for each symmetry using the reviews by Fateley *et al.* [8] and Rousseau *et al.* [9]. This requires that the site symmetry of each atom in the unit cell be known from other references [4, 5]. While there are 230 space groups in nature, the *HOC's* contain only about 39 (roughly 17%), but surely the *HOC's* contain at least 80% of the materials of optical interest in science and technology. Most of the naturally occuring minerals on Earth have orthorhombic, triclinic, or monoclinic symmetry (thus being biaxial) and have the most complicated optical properties.

On the basis of a Lorentz model for lattice vibrations, there are resonances in ϵ_I defining resonant frequencies for the lattice. The Lorentz model was developed to describe the reaction of a solid to the propagation properties of transverse EM waves in the material. We ultimately associate the resonances at ω_T with propagating transverse optical phonons in the material.

If the oscillator strength for each mode in the material is small, the real part of the dielectric constant ϵ_R is not driven negative (through zero); the medium then cannot support a propagating longitudinal electric field, and there is no ω_L. This is true for a material like polyethylene, but is not true for a material like crystalline SiO_2, where all ω_T's have accompanying ω_L's. If the material only has transverse oscillators, the irreducible representation completely describes the transverse modes giving their IR, R, and silent O activity. In fact, group theory only deals with *x, y, z* atomic displacements and seldom invokes the words transverse, longitudinal, or direction of propagation.

However, as a given oscillator strength increases, the real part of the dielectric constant will be driven to zero at a frequency defined as ω_L. This describes a propagating longitudinal mode with atomic displacements along the direction of propagation; it occurs at a frequency somewhat higher than ω_T. The ω_L mode is not necessarily counted by group theory. The ω_L mode is not directly observed as a resonant absorption line in an IR-reflection experiment, but is located at $\epsilon_R = 0$ and is found by locating the zeroes by Kramers-Kronig analysis of reflectivity R or by a Lorentz-model fit of R. Actually, the ω_L mode can be seen in a thin-film, non-normal-incidence transmission experiment [10] with *p*-polarization. It can also be inferred from reflection measurements at normal incidence as a function of crystal orientation and for a given crystal orientation as a function of angle of incidence [11].

As discussed by several authors [6, 12–14], the Raman-scattering experiment can be used to measure specific transverse and longitudinal phonons propagating in various directions in a uniaxial crystal like ZnS, for example. The principal modes are schematically represented in Fig. 1 for propagation along the *x, y,* and *z* axes, which are usually orthogonal and parallel to the

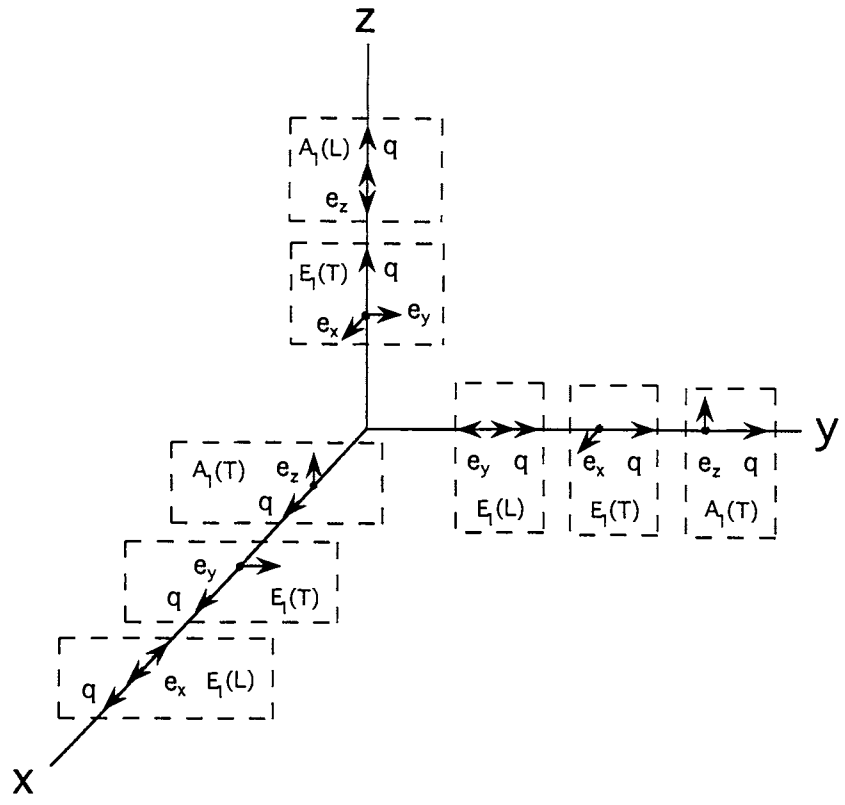

Fig. 1. Schematic representation of various A_1 and E_1 transverse and longitudinal optic modes propagating along principal directions in a CdS-type crystal. The z axis is the c optic axis. Wavevector is indicated by q and atomic displacement by e.

edges of the unit cell (except for monoclinic and triclinic symmetries). For arbitrary direction of propagation, modes are often mixed (transverse and longitudinal). For a C_{6h} crystal with hexagonal symmetry, the optic irreducible representaion is

$$\Gamma = A_1(\mathrm{IR}\|,\mathrm{R}) + 2B_1(\mathrm{O}) + E_1(\mathrm{IR}\perp,\mathrm{R}) + 2E_2(\mathrm{R}).$$

This gives 9 distinct (transverse) optic modes. The A_1 species is to be associated with e_z atomic displacements along the $z(c)$ axis, while the E_1 species is associated with e_x, e_y atomic displacements along the x and y axes. Since group theory is based on symmetry properties of atomic displacements, it tells little about direction of propagation of phonons with respect to atomic displacement of the lattice atoms. Thus, $A_1(\mathrm{IR}\|,\mathrm{R})$ can represent a transverse mode with dipole change (atomic displacement) $\|$ z. This could be a $A_1(T)$ mode propagating along x or y or an $A_1(L)$ mode propagating along z.

These three lattice vibrations have the same atomic displacement along z. Similar considerations for E_1(IR⊥,R) give an $E_1(T)$ species with atomic displacement along $x(y)$ and propagating along $y(x)$ or an $E_1(T)$ mode with atomic displacement along $x(y)$ and propagation along z; and an $E_1(L)$ with atomic displacement along $x(y)$ and propagating along $x(y)$. As mentioned before, the Raman experiment can measure each specific mode by proper orientation of the wave vectors q_i and q_s for the incident and scattered light. In the ω_T, ω_L tables, (for a non-cubic crystal), the total of optic modes will not match the number given by the irreducible representation, as the ω_L modes are "not included" in the irreducible representation.

The x, y, z axes are orthogonal. It is obvious how to define the x, y, z axes system with respect to the a, b, c edges of the unit cell for cubic, tetragonal, orthorhombic and hexagonal and trigonal symmetry (after a bit of thought). But for monoclinic and triclinic symmetries, the a, b, c axes cannot all be selected to coincide with the x, y, z system. The character tables are constructed with x, y, z axes with the resulting selection rules for IR- and Raman-active modes. However, IR experiments are often done with polarization $E \parallel a$, $E \parallel b$, $E \parallel c$. Apparently, the choice of the x, y, z coordinate system is somewhat different in Russian literature as slight systematic differences in irreducible representations seem to occur.

It is pertinent to ask which transverse and longitudinal phonons are observed in an IR reflection experiment. In Fig. 2(a) and (b) for the IR, we show typical reststrahlen reflection spectra of a CdS-type sample with the ω_T, ω_L frequencies marked for light polarizations $\parallel$ and $\perp z$. Note that ω_T (A_1) is somewhat less than ω_T (E_1); ω_L (A_1) is slightly less than ω_L (E_1). In the inset we show the experimental configuration of the sample. At the transverse frequencies light is resonantly absorbed (with a component of dipole moment $\parallel$ and $\perp z$. The longidudinal frequencies occur at the zeroes in ϵ_R. We are tempted to say that for $E \parallel z$ polarization, we measure all $A_1(T)$ modes propagating in the x-y plane; for $E \perp z$, we measure all $E_1(T)$ modes propagating in the x-z plane. Then, where are the corresponding $A_1(L)$ and $E_1(L)$ modes?

For $A_1(T)$ $(E \parallel z)$ with $q \parallel y$ and atomic dispacement $e \parallel z$, there is an $A_1(L)$ mode with $q \parallel z$ and atomic displacement $e \parallel z$. For $E_1(T)$ $(E \perp z)$ with q in the x-z plane and atomic displacement $e \parallel y$, there is an $E_1(L)$ with $q \parallel y$ and atomic displacement $e \parallel y$. A detailed examination of the several ω_T and ω_L frequencies of crystalline SiO_2 indeed suggests such a correlation.

Note that for cubic crystals the IR-active mode is always of F species in some form. Since this is a triply degenerate mode, one can always account for 2 T and 1 L modes. In non-cubic crystals the situation is more complicated. An $A_1(T)$ mode can often change species as the propagation direction is turned from z to x and, indeed, convert to an $E_1(T)$ mode.

Zone-center optic phonons which are silent or Raman active in a metal

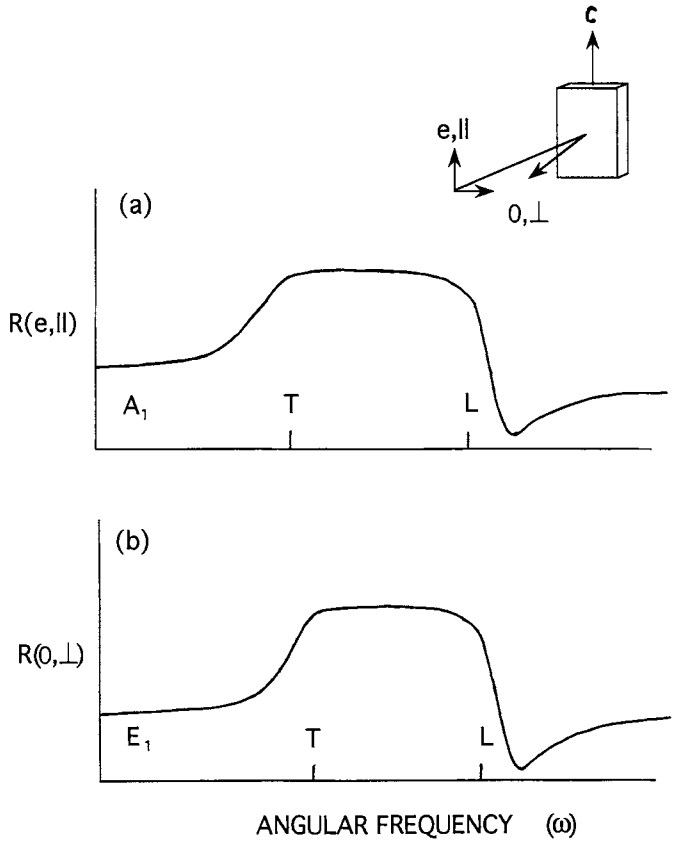

Fig. 2. (a) Reststrahlen spectrum of a CdS-type crystal for incident electric field $E \parallel c$ (extraordinary). Inset shows sample configuration with electric-field polarizations. (b) Reststrahlen spectrum of a CdS-type sample for incident electric field $E \perp c$ (ordinary).

(and therefore not possible or hard to see) can often be seen in neutron-scattering data [15, 16], at least the lower-energy modes. Note that the only metals in Table I which have IR-active modes are cubic Mn-α and the diatomic metals with cubic NaCl symmetry. Since the high free-electron concentration has driven the real dielectric function negative in the IR, these modes would be difficult to measure.

More detailed group theory can be used to calculate the dispersions curves for phonons propagating along various symmetry directions in the crystal, not just for long wavelength phonons at the zone center. This has been done in conjunction with neutron inelastic-scattering experiments. In this case, LA, TA, LO, and TO modes can be assigned to various branches of the dispersion curves in cubic diatomic metals and non-cublic metals such as Sn-β (tetragonal) [17, 18].

INTRODUCTION I

Optical data are presented below for eight metals. Mg, In, and Sn are nearly-free-electron polyvalent metals, Ti, Mn, Re, and Ru are transition metals, and Sb is not really a metal, but rather a semimetal. The optical properties of all these metals in the visible and ultraviolet are determined by interband absorption. The threshold for such absorption is, in principle, zero for the transition metals. This means that a fit of the infrared optical properties with a free-electron or Drude model may not be possible. As a practical matter, for b.c.c. and h.c.p. metals there is a threshold for the onset of strong interband absorption, but at energies below this threshold, there is dispersion in the real part of the dielectric function due to the nearby rise in the imaginary part, so a region of "pure" Drude behavior may occur only at very low energies. The polyvalent metals have, in the absence of damping, a threshold for interband absorption, but damping is always present because of electron–electron scattering. For such metals, a Drude model may be fitted at long wavelengths, but the high-energy limit of such a fit is not known reliably at this time. For these reasons we do not report the parameters of Drude fits to the infrared optical properties of any of these metals.

There are four general methods for determining the optical properties (complex refractive index $[n + ik]$ or complex dielectric function $[\epsilon = \epsilon_1 +$

HANDBOOK OF OPTICAL CONSTANTS OF SOLIDS III

$i\epsilon_2$]) of a material, and in principle, one needs two measurements at each photon energy to determine the real and imaginary parts. Three of the general methods are photometric. When using the first, one measures the reflectance of an opaque sample or thin film, and a second quantity, such as the reflectance at another angle, the transmittance of the film, or the reflectance at nonnormal incidence with a different polarization. The second method is a variant of the first. One measures the reflectance over as wide a range of energies as possible and uses a dispersion integral, or Kramers–Kronig integral, to obtain the unmeasured phase shift upon reflection. These two quantities give the complex refractive index. This method requires, in principle, data over an infinite energy range: data that are usually supplied by the use of measurements of others, and the appeal to simple models for high and low energies. The third method is ellipsometry, which measures the ratio of reflectances for *s*- and *p*-polarized radiation and the relative phase shift between the two, both measured at large angles of incidence. The fourth method is a nonoptical method, electron-energy-loss spectroscopy, which gives a spectrum proportional to $\mathrm{Im}(-1/\epsilon)$. If measured over a wide energy range, this can yield $\mathrm{Re}(-1/\epsilon)$ in a dispersion integral, and ϵ can be obtained, although a scaling factor has to be introduced to obtain absolute units. These measurement methods, and references to them, are described in more detail elsewhere [1]. In the data, we have not made use of any measurements from electron-energy-loss spectroscopy.

By now these methods are able to achieve an accuracy of the order of 1%, but there are discrepancies between the results of different investigators of over 10%. Much of this can be assigned to differences in samples, and how sample deficiencies affect the measured quantities. The first three types of measurement make use of the Fresnel relations derived from Maxwell's equations for the interface between a sample and the ambient medium, air or vacuum in the cases at hand. The interface is assumed to be a mathematical plane and the medium just below it is assumed to be the same as in the bulk of that medium. Real surfaces are not like this. They may be rather rough; the material to be studied may have an oxide film, a cold-worked layer from polishing, or both. Thin films may be highly strained and they may not have the density of the bulk. The effects of these departures from ideality are different for different techniques, and they will depend on the photon energy. For example, an oxide layer may be transparent in the visible but absorbing in the ultraviolet. As a result of these effects, there is not as good agreement between the results of different investigators as may be desired. Moreover, the "correct" optical constants one wants to use may depend on the application. Data resulting from measurements made on strained films may be the best to use if one is calculating anticipated spectra for filters made of strained films.

Several of the materials whose optical constants are given later are anisotropic. These are uniaxial, and two independent spectra of complex optical

constants are required for a complete description of the optical properties of a single crystal. For a polycrystalline sample consisting of randomly oriented crystallites, the dielectric function is given by $\epsilon = (\epsilon_{\parallel} + 2\epsilon_{\perp})/3$, with the c-axis as the reference for polarization. However, films of these materials tend not to have randomly oriented crystallites; the c-axes tend to be oriented normal to the films. They may be closer to a single crystal for optical purposes than to a polycrystal. When available, we have reported a single set of data taken on polycrystalline bulk samples, but for such anisotropic materials, most of those reported here, the reader should consult the references, and should decide how to deal with the anisotropy.

MAGNESIUM (Mg) II

Magnesium is a hexagonal close-packed metal. In single-crystal form it is optically anisotropic, uniaxial, with two independent components in the dielectric tensor, one for the electric field parallel to the c-axis and one for the perpendicular orientation. Polycrystalline films may have a texture, growing with the closest-packed plane, the basal plane, in the plane of the film, but with randomly oriented a-axes. If so, the film will be optically anisotropic. If there is truly random orientation of crystallites, the film is isotropic with a complex dielectric function $\epsilon = (\epsilon_{\parallel} + 2\,\epsilon_{\perp})/3$. Mg develops an oxide skin when exposed to air, typically MgO, which is unstable in that it does not protect the metal from further oxidation.

The data presented in Table I and Fig. 1 are those of Hagemann *et al* [1]. These are a result of a Kramers–Kronig analysis of the data of Gesell *et al.* [2], Daudé *et al.* [3], Hacman and Heitmann [4], Kröger and Tomboulian [5], and their own measurements. These represent results on polycrystalline films. Some measurements on single crystals have been published [6–8].

The location of the soft x-ray edges, shown by the short, vertical lines in Fig. 1, are taken from Siegbahn *et al.* [9].

III TITANIUM (Ti)

Ti is a hexagonal close-packed metal. In single-crystal form it is optically anisotropic, uniaxial, with two independent components in the dielectric tensor, one for the electric field parallel to the *c*-axis and one for the perpendicular orientation. Polycrystalline films may have a texture, growing with the closest-packed plane, the basal plane, in the plane of the film, but with randomly oriented *a*-axes. If so, the film will be optically anisotropic. If there is truly random orientation, the film is isotropic with a complex dielectric function $\epsilon = (\epsilon_{\parallel} + 2\epsilon_{\perp})/3$. Ti is quite reactive with air. (It is used as a getter pump in vacuum systems.) However, the oxide film is self-limiting, leading to a stable sample. Since there are so many oxides of Ti, it is difficult to model the optical properties of a Ti sample oxidized to equilibrium.

Ti is a transition metal. The incompletely filled 3*d* bands can give rise to interband optical absorption at arbitrarily small energies. This means that reliable fits of optical data to a Drude-model dielectric function cannot be made, except below some unknown low energy. Ordal *et al.* [1] were unable to fit the optical constants of Ti to a Drude model in the 1–12-μm wavelength region because of the presence of interband transitions. According to absorptivity measurements by Lynch *et al.* [2], these transitions give a strong absorption edge at 0.4 eV, although they are present, however weaker, at lower energies. Later, Ordal *et al.* [3] produced a Drude fit to the same data for energies below 0.37 eV.

Ordal *et al.* [4] measured absorptance spectra in the submillimeter-wave region and obtained optical constants by a Kramers–Kronig analysis, using their data and measurements from shorter wavelengths. The data we present in Table II and Fig. 2 are those of Ordal *et al.* [4] and Lynch *et al.* [2], measured on polycrystalline bulk samples and published by Weaver *et al.* [5], Wall *et al.* [6], and Sonntag *et al.* [7]. The last spectra were of the absorption coefficient. They were converted to spectra of the imaginary part of the complex refractive index with the assumption that the real part was unity. The data of Wall *et al.* are the only data on atomically clean surfaces. Comparison with the data of Lynch *et al.*, taken on electropolished surfaces, shows that in the vacuum ultraviolet the effect of the residual oxide is serious.

The data reported for the 1–10 μm region were taken at 4.2 K. At room temperature the peak will broaden considerably. The literature contains a number of additional reports on measurements of the optical constants of Ti [8–20] taken on bulk polycrystalline samples and on evaporated films by several techniques.

Smith [21] has measured the temperature dependence at two wavelengths, 5461 and 6328 Å.

Data in the soft x-ray region, from approximately 10^{-4} to 0.024 μm, are taken from Henke *et al.* [22], and the location of the soft x-ray edges, shown by the short, vertical lines in Fig. 1, are taken from Siegbahn *et al.* [23].

MANGANESE (Mn) IV

α-Mn has a complex unit cell, but the lattice is body-centered cubic. α-Mn, therefore, is optically isotropic. There is another cubic phase and a tetragonal phase at high temperature. Mn is quite reactive with oxygen, and this has an effect on all measurements at energies above a few electron volts. Not only does one expect a surface oxide on any film in air, but, as discussed by Atkinson [1], Mn films often contain MnO unless prepared in ultrahigh vacuum. Optical studies have not been carried out on such films.

Mn is a transition metal. The incompletely filled $3d$ bands can give rise to interband optical absorption at arbitrarily small energies. This means that reliable fits of optical data to a Drude-model dielectric function cannot be made, except below some unknown low energy.

With the exception of the work of Lenham and Treherne [2], all optical studies on Mn have been made on thin or thick films. All have possible effects from an oxide. The only infrared data are from Lenham and Treherne [2], obtained by ellipsometry on mechanically polished surfaces of bulk specimens that were not etched after polishing, and from Fouad and Amar [3], obtained on films. The latter match up well with the data of Johnson and Christy [4], taken in the 1–6-eV range on thin films. We present data in Table III and Fig. 3 from both these sources, and the soft x-ray absorption measurements of Sonntag *et al.* [5]. The latter were measurements of the absorption coefficient, converted to a spectrum of the imaginary part of the refractive index with the assumption that the real part was unity. There is a gap between these measurements and the data of Christy *et al.* [4]. In addition, there have been measurements by Steel [6] and Aagard [7].

Data in the soft x-ray region, from approximately 10^{-4} to 0.024 μm, are

taken from Henke *et al.* [8], and the location of the soft x-ray edges, shown by the short, vertical lines in Fig. 3, are taken from Siegbahn *et al.* [9].

RUTHENIUM (Ru) V

Ruthenium is a hexagonal close-packed metal. In single-crystal form it is optically anisotropic, uniaxial, with two independent components in the dielectric tensor, one for the electric field parallel to the *c*-axis and one for the perpendicular orientation. Polycrystalline films may have a texture, growing with the closest-packed plane, the basal plane, in the plane of the film, but with randomly oriented *a*-axes. If so, the film will be optically anisotropic. If there is truly random orientation, the film is isotropic with a complex dielectric function $\epsilon = (\epsilon_{\parallel} + 2\epsilon_{\perp})/3$.

Ru is a transition metal. The incompletely filled 4*d* bands can give rise to interband optical absorption at arbitrarily small energies. This means that reliable fits of optical data to a Drude-model dielectric function cannot be made, except below some unknown low energy.

Reliable optical data over a wide spectral range do not exist for polycrystalline bulk samples or thin films of Ru. Therefore, we have chosen to use data taken from the basal plane of a single crystal ($\mathbf{E}\perp\mathbf{c}$) by Weaver *et al.* [1, 2]. These data are from a Kramers–Kronig inversion of absorptance and reflectance data. Where there is overlap of spectral regions, there is good agreement with the data of Kirillova *et al.* [3] obtained by ellipsometry, and with Cox *et al.* [4] from reflectance measurements on films taken at several angles of incidence. Additional measurements have been made by Kress and Lapeyre [5], and by Carroll and Melmed [6].

Data in the soft x-ray region, from approximately 10^{-4} to 0.024 μm, are taken from Henke *et al.* [7], and the location of the soft x-ray edges, shown by the short, vertical lines in Fig. 4, are taken from Siegbahn *et al.* [8]. In order to fill the small gap between the data of Henke *et al.* [7] and Weaver *et al.* [1, 2], we have incorporated some of the data of Cox *et al.* [4].

INDIUM (In) VI

Indium is a tetragonal metal. Its softness and low melting point are well known. In single-crystal form it is optically anisotropic and uniaxial, with two independent components in the dielectric tensor, one for the electric field parallel to the *c*-axis and one for the perpendicular orientation. Polycrystalline films may have a texture, growing with the closest-packed plane, the basal plane, in the plane of the film, but with randomly oriented *a*-axes. If so, the film will be optically anisotropic. If there is truly random orientation, the film is isotropic with a complex dielectric function $\epsilon = (\epsilon_{\parallel} + 2\epsilon_{\perp})/3$. Indium develops an oxide skin when exposed to air.

We present data in Table V and Fig. 5 for polycrystalline In, usually in the form of evaporated films. The film textures usually have not been determined. Studies of the anisotropy in single crystals have been carried out by Lenham and Treherne [1, 2], but on "hand-polished" single crystals. We list the infrared data of Golovashkin *et al.* [3], the visible and ultraviolet data of

Koyama *et al.* [4], and the vacuum ultraviolet and soft x-ray data of Hunter *et al.* [5, 6], Jezequel *et al.* [7], and Leveque *et al.* [8]. All these were taken on evaporated films. The last two references contain spectra of the absorption coefficient that have been converted to spectra of the imaginary part of the refractive index with the assumption that the real part is unity. Other measurements in the visible and near-ultraviolet region are found elsewhere [9–12], and additional measurements in the vacuum ultraviolet are reported by others [13–15]. Measurements at several temperatures were made by Golovashkin *et al.* [3] and Mathewson and Myers [12]. Hodgson [16] and Wilson and Rice [17] have made optical measurements on liquid In.

Data in the soft x-ray region, from approximately 10^{-4} to 0.024 μm, are taken from Henke *et al.* [18], and the location of the soft x-ray edges, shown by the short, vertical lines in Fig. 5, are taken from Siegbahn *et al.* [19].

VII TIN (Sn)

White tin, β-Sn, is a tetragonal metal. There is also a cubic phase, gray tin, α-Sn, with the diamond structure. Gray tin is the stable form below 18° C, but the transformation from white tin to gray tin is sluggish. We consider here only white tin. In single-crystal form it is optically anisotropic and uniaxial, with two independent components in the dielectric tensor, one for the electric field parallel to the *c*-axis and one for the perpendicular orientation. Polycrystalline films may have a texture, growing with the closest-packed plane, the basal plane, in the plane of the film, but with randomly oriented *a*-axes. If so, the film will be optically anisotropic. If there is truly random orientation, the film is isotropic with a complex dielectric function $\epsilon = (\epsilon_{\parallel} + 2\epsilon_{\perp})/3$. Sn develops an oxide skin when exposed to air, typically SnO_2 with a layer of SnO below.

The data reported in Table VI and Fig. 6 were taken on polycrystalline films. However, it is not at all clear that these films had randomly oriented grains. Schwartz [1] made ellipsometric measurements on an oriented single crystal and a polycrystalline film, and it is clear from his data that the spectrum of the film is neither that for **E** in the basal plane nor the polycrystalline average quoted above. Also, the structures in the spectra for the film are broader than those for the single crystal. The data are taken from Golovashkin and Motulevich [2, 3], MacRae *et al.* [4], Girouard and Truong [5], Jezequel *et al.* [6], and Haensel *et al.* [7]. The last have reported only absorption-coefficient spectra. These have been converted to spectra of the imaginary part of the refractive index with the assumption that the real part is unity. Other measurements have been reported by Lenham and Treherne [8] and Mahmoud [9].

Carotenuto *et al.* [10] measured the temperature derivative of the optical constants. Optical studies at different temperatures have been carried out by Schwartz [1] and Golovashkin and Motulevich [2, 3]. Hodgson [11], Comins [12], and Petrakian *et al.* [13] have measured the optical constants of liquid Sn.

Data in the soft x-ray region, from approximately 10^{-4} to 0.024 μm, are taken from Henke *et al.* [14], and the location of the soft x-ray edges, shown by the short, vertical lines in Fig. 6, are taken from Siegbahn *et al.* [15].

VIII ANTIMONY (Sb)

Antimony is a semimetal with a rhombohedral structure. In single-crystal form it is optically anisotropic and uniaxial, with two independent components in the dielectric tensor, one for the electric field parallel to the *c*-axis and one for the perpendicular orientation. Polycrystalline films may have a texture, growing with the closest-packed plane, the basal plane, in the plane of the film, but with randomly oriented *a*-axes. If so, the film will be optically anisotropic. If there is truly random orientation, the film is isotropic with a complex dielectric function $\epsilon = (\epsilon_{\parallel} + 2\epsilon_{\perp})/3$. Sb develops an oxide skin when exposed to air.

Cardona and Greenaway [1] have determined optical constants for a single crystal of Sb with **E** in the basal plane ($\mathbf{E} \perp \mathbf{c}$). We give their data in Table VII and Fig. 7. Data in a more limited, but overlapping, range have been taken by Aspnes [2], Strümpler and Lüth [3], and de Sande *et al.* [4]. Lenham and Treherne [5] and Lenham *et al.* [6] have made measurements in the infrared. Nanney [7] measured the infrared absorptance spectra of a single crystal with $\mathbf{E} \perp \mathbf{c}$ and $\mathbf{E} \parallel \mathbf{c}$ at 300 K and 4.2 K.

Data in the soft x-ray region, from approximately 10^{-4} to 0.024 μm, are taken from Henke *et al.* [8], and the location of the soft x-ray edges, shown by the short, vertical lines in Fig. 7, are taken from Siegbahn *et al.* [9].

IX RHENIUM (Re)

Rhenium is a hexagonal close-packed metal. In single-crystal form it is optically anisotropic and uniaxial, with two independent components in the dielectric tensor, one for the electric field parallel to the *c*-axis and one for the perpendicular orientation. Polycrystalline films may have a texture, growing with the closest-packed plane, the basal plane, in the plane of the film, but with randomly oriented *a*-axes. If so, the film will be optically anisotropic. If there is truly random orientation, the film is isotropic with a complex dielectric function $\epsilon = (\epsilon_{\parallel} + 2\epsilon_{\perp})/3$.

Re is a transition metal. The incompletely filled 5*d* bands can give rise to interband optical absorption at arbitrarily small energies. This means that reliable fits of optical data to a Drude-model dielectric function cannot be made, except below some unknown low energy.

Reliable optical data over a wide spectral range do not exist for polycrystalline bulk samples or thin films of Re. Therefore, for Table VIII and Fig. 8, we have chosen to use data taken from the basal plane of a single crystal ($\mathbf{E}\perp\mathbf{c}$) by Weaver *et al.* [1, 2]. In the soft x-ray region the absorption-coefficient spectra of Haensel *et al.* [3] have been converted to spectra of the imaginary part of the complex refractive index with the assumption that the real party is unity. Additional optical measurements have been made by Nomerovannaya *et al.* [4] and others [5–8]. Nomerovannaya *et al.* made measurements at 295 and 77 K. Barnes [9] has made measurements of the temperature dependence at higher temperatures.

Data in the soft x-ray region, from approximately 10^{-4} to 0.024 μm, are taken from Henke *et al.* [10], and the location of the soft x-ray edges, shown by the short, vertical lines in Fig. 8 are taken from Siegbahn *et al.* [11].
